[a]Responses used for this estimate included 25 not overweight Black women, 44 overweight Black women, 56 not overweight White women, and 64 overweight White women.

*$P < .05$ (within race groups).

Methods

Participants in the Charleston Heart Study constitute a probability sample, recruited in 1960, of residents of Charleston County, South Carolina, over the age of 65. The data used in the present study were taken from the 1991 reinterview of 517 women from 66 to 105 years of age in the Charleston Heart Study.[19] Complete nutrition information was collected from 404 women (278 White and 126 Black). The mean age of these 404 women was 3 years younger than that of the women for whom only incomplete data were available (73 years vs 76 years; $P < .001$).

A questionnaire was developed and tested to examine attitudes toward eating, body size perceptions, and dieting practices. Some items were adapted from other surveys.[5,20-22] Line drawings of women[20] ranging from very thin to obese (scored 1 to 9) were used to measure perceptions of actual and ideal body size. A body size discrepancy score was calculated as the difference between the perceived actual and ideal size.

All items were pretested by means of in-depth interviews. Test–retest reliability was determined in 50 subjects older than 65 years of age over a period of 3 to 6 weeks. The mean kappa values were 0.6 for items concerning attitudes toward eating and 0.7 for questions on body size perceptions, indicating good reproducibility.[23]

A body mass index of 27.3 kg/m^2 was used as a cutpoint to indicate overweight.[24] Women with body mass indexes of less than 27.3 kg/m^2 are referred to here as "not overweight."

Statistical analyses included the two-sample t test, analysis of variance, chi-square tests, and multivariate logistic regression. A frequency count of 1 was

TABLE 2—Odds Ratios for Eating Restraint and Body Image in Overweight Black vs Overweight White Women

	Odds Ratio	95% Confidence Interval
Eating restraint		
Ever eaten less than you wanted to keep weight down	0.9	0.7, 1.4
Feel guilty after overeating	0.6	0.4, 0.9
Ever dieted to lose weight	0.4	0.2, 0.7
Body image		
As adult, tried to gain weight	0.8	0.4, 1.6
Believe that extra weight at older ages is good	0.6	0.4, 0.9
Satisfied with current weight	2.5	1.7, 3.7
Consider yourself overweight	0.3	0.1, 0.5
Spouse/significant other thinks you are overweight[a]	0.9	0.5, 2.0
Rate your figure somewhat attractive or attractive	2.7	1.7, 4.1

Note. Odds ratios and 95% confidence intervals are adjusted for body mass index, age, and education. Overweight White women were used as the reference group.

[a]Responses used for this estimate included 44 overweight Black women and 64 overweight White women.

given to empty cells for the estimate of odds ratios.

Results

The mean body mass index was 23 kg/m^2 in Black and White women who were not overweight, but overweight Black women were an average of one body mass index unit heavier than overweight White women (33 kg/m^2 vs 32 kg/m^2; $P < .01$). Sixty-five percent of the Black women and 35% of the White women were in the overweight category. Four percent of both Black and White women were underweight (i.e., had a body mass index less than or equal to 19.1 kg/m^2). Black women had fewer years of education than White women (7 years vs 11 years; $P < .001$). Educational attainment did not differ between the weight categories within racial groups.

Tables 1 and 2 show responses to nine items for Black and White women within weight categories. Odds ratios comparing the responses of women in different weight status and race categories are shown. In both racial groups, overweight women reported more dieting and less satisfaction with their body size.

Table 3 compares perceptions and ideals of body size by race and weight status. The overall effects of race and weight status were statistically significant for all but one comparison. Responses of African-American women indicated that they were more satisfied with their body size than were White women. Responses of overweight women indicated that their ideal body mass index was higher by 4.9 kg/m^2 than that of women who were not overweight. In fact, the mean ideal body mass index calculated for overweight Black women—28.7 kg/m^2—would be categorized as overweight using the National Center for Health Statistics cut-point of 27.3 kg/m^2. Among African-American women, the percentage who considered their figures attractive was unrelated to the percentage who were overweight.

Discussion

In this study, body size perceptions and attitudes toward eating differed by both weight status and race in an elderly cohort. The differences between women who were and were not overweight agree with those found in previous studies of exclusively or predominantly young women, which have shown that obese women (both Black and White) are more likely than thin women to report eating restraint.[5,25,26] The differences between African-American and White women in body size perceptions were striking and suggest underlying differences in cultural attitudes toward overweight in this cohort.

Insights into the possible nature of this difference in cultural attitudes come from nutritional anthropological studies of attitudes toward obesity[15,27] and studies of socioeconomic factors in obesity.[28,29] Positive attitudes toward being moderately overweight are characteristic of economically disadvantaged societies in which thinness is a sign of poor health. Theoretically, differences in body weight between Black and White women will be reduced as African Americans gain greater social and economic advantages. However, movement of African-American women toward the attitudinal profiles of White women is not necessarily desirable. Black women who are not overweight are less likely to have an inappropriate body image. The challenge to the public health community is to encourage weight reduction when appropriate without forcing on Black women a negative self-image and a neurotic preoccupation with weight. □

The 1966 Enactment of Medicare: Its Effect on Discharges from Los Angeles County–Operated Hospitals

Peter A. Glassman, MD, MSc, Robert M. Bell, PhD, and Robert E. Tranquada, MD

ABSTRACT

The effect of Medicare on two public hospitals in Los Angeles County was analyzed by examining the percentage of patients 65 years of age and older among all discharges from 1958 through 1971. At Harbor General Hospital, discharges of elderly patients had dropped from 21.7% to 7.9% by late 1966; at Los Angeles County General Hospital, discharges decreased from 15.3% to 10.7% between 1966 and 1967. Monitoring public hospitals' demographic changes after enacting a national health plan may provide information on patients' and providers' acceptance of insurance and on resources needed by public hospitals to care for those left without coverage. (*Am J Public Health.* 1994;84:1325–1327)

Introduction

A major debate shaping US health care policy centers on the optimal mix of public and private insurance needed to finance care for nearly 37 million uninsured Americans. Proposed legislation includes employer-based insurance, single payer universal coverage, and expansion of Medicaid. There is controversy about the effects that any of these options would have on those currently uninsured.

In considering the potential effects of health reforms, it is important to examine the role of public hospitals, which currently serve a disproportionate share of the uninsured and underinsured. In this regard, an instructive chain of events began on July 1, 1966, when Medicare began providing health insurance for many previously uninsured elderly people. Prior to Medicare, an estimated 56% to 75% of the nation's elderly had inadequate health insurance, and many depended on public hospitals for medical care.[1–4]

Information on how Medicare has affected public hospitals is somewhat sparse.[5,6] In New York City, indirect information indicates that, by 1975, a large proportion of Medicaid and Medicare recipients were receiving care in the private sector. The exact timing and the magnitude of the change from public to private care are not clear, however.[7]

This study examined the effect of Medicare enactment on discharges of elderly patients (those 65 years of age and older) from the two county-operated acute hospitals in Los Angeles County. We hypothesized that health insurance for uninsured and underinsured elderly people produced a rapid and permanent shift of these patients into the private sector.

Methods

Data were collected from the stored records of Los Angeles County General Hospital (now Los Angeles County/

Note. ○ = Harbor General Hospital; △ = Harbor General Hospital, July to December only; + = Los Angeles County General Hospital.

FIGURE 1—Percentage of elderly discharges: Los Angeles County General Hospital and Harbor General Hospital, 1958 through 1971.

University of Southern California Medical Center) and Harbor General Hospital (now Los Angeles County Harbor/University of California at Los Angeles Medical Center). We computed the percentage of elderly patients among all discharges (including deaths) for the years 1958 through 1971. Data were not available for Harbor General Hospital for 1958, 1959, 1965, and the first 6 months of 1963 and 1966.

We conducted time series analyses for each hospital to determine whether (1) there was a trend in the proportion of discharges of elderly patients prior to Medicare and (2) the Medicare program altered the trend.

To separate a possible Medicare-induced drop from an overall downward trend in discharges from 1958 to 1971, we fit the Los Angeles County General Hospital data to a linear regression model that allowed for distinct slopes during the periods 1958 through 1962, 1963 through 1966, and 1967 through 1971 and allowed for shifts at 1963 and 1967. (We did not do so for Harbor General because of the missing data.) This allowed evaluation of the average percentage change in discharges per year during the three time periods (linear trends). Two-tailed t tests were used in determining significant regression coefficients.

Results

For both hospitals, there was a downward trend in the percentage of elderly discharges beginning in 1963 and continuing up until Medicare enactment (Figure 1). At Harbor General, a dramatic drop from 21.7% to 7.9% occurred between the end of 1964 and 1966. At County General, the drop from 15.3% to 10.7% appears to have occurred later, between 1966 and 1967. The shift at County General, after controlling for the pre- and post-Medicare trends, was 3.55% ($t = -7.9$, $P < .001$); the shift at 1963 was not statistically significant. The slopes of the downward trends from 1958 to 1962 and from 1967 to 1971 were −0.7% ($t = -4.7$, $P = .002$) and −0.8% per year ($t = -7.4$, $P < .001$), respectively. The pre- and post-Medicare slopes did not differ significantly from each other. By 1971, the proportions of elderly discharges at County General and Harbor General had fallen to 7.5% and 5.6% of total discharges, respectively.

Discussion and Conclusions

Medicare enactment was associated with a large drop in the number of elderly patients being cared for in Los Angeles' county-operated hospitals, even as the population of those 65 years of age and older in Los Angeles County increased by nearly 100 000 during the 1960s.[8,9] Elderly patients currently account for about 4% of total discharges from Los Angeles County hospitals, indicating that the effect of Medicare was not a temporary phenomenon.[10]

The downward trend occurring before Medicare at Los Angeles County General may be due to the Kerr-Mills legislation implemented in California in 1962. This legislation allowed some indigent elderly patients to receive care in private settings but, because of its limited coverage, would not likely explain the large patient shift seen during the period from 1965 to 1967.

Not all elderly patients left the county-operated hospital system after the implementation of Medicare. Possible reasons include the following: (1) County hospitals provided the nearest comprehensive care facility; (2) some patients were ineligible for Medicare; (3) some patients voluntarily continued their care at a county hospital; and (4) some recipients received emergency inpatient care at county hospitals. Lack of adequate local private providers also could have been a factor. A combination of these elements may explain the smaller initial decrease seen at County General, which served a larger and poorer section of Los Angeles than did Harbor General. Other barriers to obtaining care, such as transportation and language difficulties, may also have affected accessibility to private services.

As mentioned earlier, a significant movement of elderly patients away from Los Angeles County hospitals occurred after the implementation of Medicare. Although confirmatory data from private institutions are unavailable, it appears that many newly insured elderly people quickly opted for care at private facilities and offices where they perceived that a higher quality of care was available.

Medicare enactment thus caused a differential impact on the private and public sectors, a scenario that will probably be repeated if proposed reforms do not succeed in implementing health coverage for all. Those who do receive coverage (i.e., those who are employed but not insured), assuming that private providers accept it, will probably be absorbed into fee-for-service or managed care. Public hospitals will be left to provide care for the remainder of the population: those who are unemployed, part-time laborers, those who are ineligible, and immigrants. The way in which public hospitals adapt to the change in case mix, funding, and

patient needs may be as important to the success of health reform as the overall reform package itself. Public hospitals will probably need assistance in defining their role and function in a system of managed competition. They will need to be monitored and, if necessary, allocated new resources to ensure that they will be able to continue offering appropriate care to those in need. □

Sociodemographic and Health Factors in Driving Patterns after 50 Years of Age

Raynard Kington, MD, PhD, David Reuben, MD, Jeannette Rogowski, PhD, and Lee Lillard, PhD

ABSTRACT

Data from the 1990 Panel Study of Income Dynamics were used to predict, by means of logistic regression, the likelihood that people who had previously driven would continue to drive and to drive after dark after 50 years of age. The results support the conclusion that driving patterns appear to be explained partly by a combination of sociodemographic factors and health status. Furthermore, it is shown that those reported to drive for nondrivers appear to be the same individuals known to provide most informal support for functionally impaired elderly people. (*Am J Public Health.* 1994;84:1327–1329)

Introduction

As the ranks of older Americans grow, more older people will be driving. Using a population-based study sample that included a substantial representation of older African Americans, we attempted to answer the following questions: What sociodemographic, economic, and health factors are associated with driving and driving after dark among older people? Among older people who do not drive, who assumes responsibility for driving them?

Methods

This study was based on reports of driving habits from a 1990 health supplement questionnaire mailed to household heads and spouses more than 50 years of age taking part in the nationally representative Panel Study of Income Dynamics.[1] Of the 3277 individual eligible household heads and spouses, 2429 (74%) completed surveys.

Sociodemographic variables studied in this analysis included age, sex, race, education, marital status, gross income of head of household and spouse (in 1988), number of adults in the household, urbanicity of the county of residence, and region of the country. Health status was measured by three multi-item subscales based on the RAND SF 36 health survey: general health perceptions and physical and emotional role functioning (higher scores indicate better health status for each index).[2] Functional status was measured by reported limitations in the following activities of daily living and instrumental activities of daily living: bathing, dressing, toileting, transferring, walking inside the home, eating, doing light housework, preparing meals, doing laundry, shopping for groceries, managing money, taking medications, and telephoning. Also, the presence of the following self-reported chronic medical conditions was noted: arthritis, hypertension, hearing impairment, visual impairment, con-

Note. Race, geographic region (South [omitted category: Northeast]), number of children in household, 1988 household income, dummy variables for activities of daily living and instrumental activities of daily living, an index for physical role functioning, and dummy variables for congestive heart failure, hypertension, hearing impairment, cancer, and angina were also controlled. Only adjusted odds ratios for significant coefficients in either equation are presented. The age category 50–59 years was omitted.

[a]Estimated by multivariate logistic regression.

[b]Adjusted odds ratio for an index that takes on values from 5–25 (higher score means better health) (thus, the adjusted odds ratio for a one-unit change in the index).

[c]Adjusted odds ratio for an index that takes on values from 0–3 (higher score means better health).

gestive heart disease, diabetes mellitus, angina, and major neurological impairment. Respondents were asked whether they drove and, if they did, whether they drove after dark. If they did not drive, they were asked whether they had ever driven and, if so, when they had stopped driving and their reasons for doing so.

Logistic regression was used to estimate the likelihood of a respondent reporting driving in 1989 and driving after dark. People who had never driven or who had stopped driving before 50 years of age were excluded from these analyses. Individual observations in the regressions were weighted by a function of the probability of being included in the original Panel Study of Income Dynamics sample, continuing in the follow-up sample through 1990, and responding to the mail-out survey.

Results

Table 1 describes the study population. Of the 2429 respondents, 1716 (71%) reported driving in 1989, and 1442 (84%) of these individuals reported driving after dark. Of those 577 who did not drive, about half (284) had never driven. The average age at which former drivers had stopped driving was 60 years. The most common reasons for stopping were a health problem other than eyesight or hearing impairment (30%), "trouble with eyesight" (29%), and "not comfortable driving" (27%). Only 4% reported having their driver's license revoked. Eighteen percent and 15%, respectively, reported that they could not afford a car and the accompanying insurance premiums. For those who did not drive, the sources of transportation were an adult child (39%), a spouse (21%), a sibling (7%), other relatives (24%), a friend (23%), and taxi drivers or other paid individuals (15%).

Table 2 presents significant coefficients ($P \leq .05$) for logistic regressions estimating the likelihood that an individual reported driving or driving after dark in 1989. Older people, women, and those in more urban counties and in households with more adults were less likely to drive, and better educated and married individuals and residents of the West and North Central regions were more likely to drive. Individuals with better self-reported general health were more likely to drive, but physical and emotional role functioning were not significant predictors of driving. The only activities of daily living or instrumental activities of daily living with significant

coefficients were "difficulty with taking medications" and "difficulty with preparing meals," and those with the latter condition were more likely to drive. Of the medical conditions, individuals with major neurological conditions and visual impairment were significantly less likely to drive, and those with arthritis were more likely to drive. The pattern of predictors of not driving after dark was similar to that for the predictors of not driving. The self-perceived health index, marital status, the number of adults in the household, and the regional dummies, however, were not significant predictors of driving after dark. People with diabetes and with worse scores on the emotional role functioning index were more likely to restrict driving after dark.

Discussion

The patterns of association between driving and sociodemographic factors were similar to those found in previous research.[3-5] Of note was the new finding that individuals who lived in households with more adults were less likely to drive. This pattern may reflect the choice of elderly people to stop driving when other adults are readily available to drive or the decision of those who can no longer drive to choose living arrangements that provide them a larger pool of potential drivers on which to draw.

Multivariate analyses of the contribution of health status in explaining driving patterns revealed that few of the self-reported functional and health status measures were predictors of driving patterns. Instead, a combination of the sociodemographic variables, an index of self-perceived health, and three medical conditions—visual impairment, arthritis, and major neurological impairment—explained much of the variation.

Surprisingly, the presence of arthritis was associated with a higher probability of continuing driving. Perhaps other modes of transportation (e.g., most buses) are so poorly suited to accommodate those with functional limitations due to chronic arthritis that they continue driving as the least difficult means of reliable transportation.

Restricting driving after dark is often an intermediate step in self-regulation of driving before complete discontinuation. In the equations for predicting driving after dark, the presence of diabetes, which may lead to visual impairment, also led to a greater likelihood of restricting such driving.

Driving patterns appear to be explained partly by a combination of sociodemographic factors and health status. Our results go beyond previous research in defining more precisely various dimensions of health and socioeconomic status and in controlling for regional characteristics such as urbanicity. Furthermore, the results show that those reported to drive for nondrivers appear to be the same individuals known to provide most informal support for functionally impaired elderly people.[6] □

The *American Journal of Public Health* (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. Michael Sprafka, PhD, Rita Weisbrod, PhD, and Henry Blackburn, MD

ABSTRACT

Objectives. The Minnesota Heart Health Program is a 13-year research and demonstration project to reduce morbidity and mortality from coronary heart disease in whole communities.

Methods. Three pairs of communities were matched on size and type; each pair had one education site and one comparison site. After baseline surveys, a 5- to 6-year program of mass media, community organization, and direct education for risk reduction was begun in the education communities, whereas surveys continued in all sites.

Results. Many intervention components proved effective in targeted groups. However, against a background of strong secular trends of increasing health promotion and declining risk factors, the overall program effects were modest in size and duration and generally within chance levels.

Conclusions. These findings suggest that even such an intense program may not be able to generate enough additional exposure to risk reduction messages and activities in a large enough fraction of the population to accelerate the remarkably favorable secular trends in health promotion activities and in most coronary heart disease risk factors present in the study communities. (*Am J Public Health.* 1994;84:1383–1393)

Introduction

Cardiovascular diseases, principally coronary heart disease and stroke, remain the leading causes of death and disability in industrialized countries. They are preventable and reversible through the modification of risk factors, including elevated blood lipids, elevated blood pressure, cigarette smoking, and sedentary life-style.[1–4] Entire populations are at increased risk because of mass elevated risk factors in which individual susceptibility is enhanced by culture, economic factors, and the environment. Population risk should be amenable to change through communitywide strategies,[5] and several community intervention research and demonstration projects are under way or completed in the United States and Europe.[6–12]

The largest of these studies in the United States is the Minnesota Heart Health Program. Initiated in 1980, the Minnesota Heart Health Program involves approximately 400 000 persons in six communities in the Upper Midwest. It was hypothesized that a 5- to 6-year intervention program would (1) improve health behaviors; (2) lower population levels of blood cholesterol by 7 mg/dL, blood pressure by 2 mm Hg, and cigarette smoking by 3% and increase population physical activity levels by 50 kcal/day; and (3) that these changes would subsequently reduce cardiovascular disease morbidity and mortality by 15%. Risk factor levels and associated behaviors were measured before the start of the intervention program and annually for 6 or 7 years of follow-up in all six communities; morbidity and mortality data are being collected annually from the six communities and surrounding states. The purpose of this paper is to present the main risk factor results of the study.

Methods

Study Design

The design of the Minnesota Heart Health Program is described elsewhere[6] and summarized here (Figure 1). Three pairs of communities were selected; each pair had one education site and one

comparison site matched on size (25 000–110 000), community type (small, medium, urban), and distance from the Minneapolis–St. Paul metropolitan area (<250 miles). Assignment of communities to intervention within pairs was nonrandom and completed before collection of the data. After a 16-month baseline period, a 5- to 6-year intervention program was introduced in November 1981 in Mankato, Minnesota, a rural community in southern Minnesota. The program was introduced 22 and 28 months later, respectively, in Fargo–Moorhead, an urban area consisting of two neighboring communities along the North Dakota–Minnesota border, and in Bloomington, Minnesota, a large Minneapolis–St. Paul suburb. The staggered entry allowed for gradual development of the intervention program and strengthened the design through replication; it also provided two, three, and four baseline surveys in the first, second, and third pairs, respectively, to improve the precision of the preintervention time trends estimated from the data.

Survey Methods

Cross-sectional surveys. Cross-sectional surveys of 300–500 randomly selected adults were conducted periodically in each community, with a two-stage cluster sampling design.[13] Initially, census blocks were randomly selected from each city, with the probability of selection proportional to the expected number of households. Geographically adjacent groups of five households were randomly selected from within those blocks. Within households, a single age-eligible adult was selected at random. This procedure was repeated for the second survey sample; subsequent samples were drawn from the census blocks selected in the first 2 years. Matched communities were surveyed in adjacent 2-month periods.

After selection, initial household contact was by letter, followed by direct interview to (1) enumerate the household; (2) randomly select one age-eligible subject; (3) collect data on sociodemographic characteristics, medical history, health attitudes and beliefs, and smoking history; and (4) extend an invitation to visit a survey center for risk factor measurements. Those who spoke no English or who were judged mentally incompetent to participate were ineligible (<5%), and some participants were examined at home (<5%).

Cohort surveys. Periodic remeasurements were made in a cohort comprised of participants selected at random from all of the preintervention cross-sectional surveys. To minimize the effect of repeated testing, remeasurements were structured so that approximately half the cohort was selected at random for recontact after 2 years of intervention, whereas the other half was recontacted after 4 years. The entire cohort was recontacted after 6–7 years of intervention. As expected, there were no differences in baseline risk factors between the two halves of the cohort.

Measurements

Detailed methods for risk factor measurements are reported elsewhere[14] and are only summarized here.

Blood pressure was measured in a seated position with a random-zero sphygmomanometer (Hawksley–Gelman, London, England) and an appropriate-sized cuff after a 5-minute rest. Two measurements of systolic and fifth-phase diastolic pressure were made 1 minute apart and averaged for the analysis.

Blood was obtained according to the methods described in the Lipid Research Clinic's protocol.[15] Serum total cholesterol was measured in the Minnesota Lipid Research Clinic's laboratory by an Autoanalyzer II (Technicon Instrument

[a]Negative values refer to observations made before the intervention program; a value of 0 refers to observations made immediately before the intervention program; positive values refer to observations made after the intervention program began.
[b]Data were not collected from Mankato, Winona in E-3 or E-2, nor in Fargo/Moorhead, Sioux Falls in E-3; pooled means for E-3 and E-2 were calculated after imputing values for the missing components based on the differences in the city levels as estimated in the regressions.

Corporation, Tarrytown, NY).[16] Quality control of Lipid Research Clinic laboratories was maintained by external standardization with the Centers for the Disease Control (CDC),[16] and the values were adjusted for daily variability against standard CDC pools.[17]

Participants were classified as current smokers if they had ever smoked at least 100 cigarettes in their lifetime and smoked at present. Serum thiocyanate was also measured.[18]

Height and weight were measured in stocking feet and light clothing. Height was measured to the nearest centimeter with a fixed metal rule. Weight was measured to the nearest half pound with a balance beam scale. Body mass index was computed as kilograms per square meter.

Leisure time physical activity was assessed as the percentage of participants who answered "yes" to the question, "Are you regularly active in your leisure time?"

A risk reduction exposure score, which was constructed from 10 questions about recent participation in activities such as smoking cessation classes, cholesterol screening, and so forth, was added when intervention began. The score ranged from 0 to 10, and all items were designed to be equally applicable in all communities.

Other variables were employed as stratification factors (age, gender, educational attainment) or as covariates (specific to each outcome and identified in Figures 2–10).

Scores for the risk per 1000 persons of death from coronary heart disease in 10 years were computed according to the method of Truett et al.[19] with the coefficients provided by Leaverton et al.[20]; separate functions were used for men and women.* The variables included were age in years, systolic blood pressure, total cholesterol, and cigarette smoking.

Intervention Methods

The Minnesota Heart Health Program intervention advocated hypertension prevention and control, healthy eating patterns for lower blood cholesterol and blood pressure, nonsmoking, and regular physical activity. It operated at the individual, group, and community levels and embraced a wide range of strategies and theories, including social learning theory,[21] persuasive communications theory,[22,23] and models for involvement of community leaders and institutions.[24] The program alerted people to health issues, informed them of effective behavioral alternatives for health promotion, provided incentives for new behaviors, and provided reinforcements to maintain new behaviors.

Community analysis and organization methods were used to engage community leaders and organizations as active participants in the intervention programs; this effort resulted in their active involvement, gradual environmental change to support risk reduction, and community planning for program continuation.[25–27] Mass media were used to increase individual exposure to the Minnesota Heart Health Program risk factor messages, establish awareness of the program, and increase the salience of the program

*Risk = $1000 * (1/1 + e^{-c})$.
For men: $c = -9.42705 + 0.0644(\text{age}) + 0.0131(\text{SBP}) + 0.0046(\text{CHOL}) + 0\ 7809(\text{SMK})$.
For women: $c = -15.1298 + 0.1059(\text{age}) + 0.0223(\text{SBP}) + 0.0097(\text{CHOL}) + 0.8823(\text{SMK})$.

FIGURE 3—Total cholesterol: results of the MHHP education intervention program.

messages.[28–32] Health professionals in the education communities were involved through their local organizations and preventive practice advisory committees, and they served as role models and opinion leaders.[33,34] Systematic risk factor screening and education were conducted during the first 3 years of the intervention program; over 60% of all adult residents received on-site measurement, education, and counseling.[35] The adult education component made available personal, intensive, and multiple contact programs to reduce cardiovascular risk; this strategy focused on self-management and included changes in existing behaviors, in the meaning of those behaviors, and in the environmental cues that supported those behaviors.[36–44] Direct education programs for school-age children discouraged health-compromising behaviors and promoted health-enhancing behaviors in youth and their parents.[45–47]

The program included a high-intensity campaign via the mass media, recruited virtually all primary care physicians and many other health professionals to training programs, recruited more than 60% of all adults age 25–74 to the screening and education programs, recruited more than 30% of all adults to

[a]Negative values refer to observations made before the intervention program; a value of 0 refers to observations made immediately before the intervention program; positive values refer to observations made after the intervention program began.
[b]Data were not collected from Mankato, Winona in E-3 or E-2, nor in Fargo/Moorhead, Sioux Falls in E-3; pooled means for E-3 and E-2 were calculated after imputing values for the missing components based on the differences in city levels as estimated in the regressions.

face-to-face intervention programs, involved organizations in environmental change programs, and involved most of the resident youth in school-based health promotion activities.

Analysis Methods

By design, the community was the unit of assignment, whereas the individual was the unit of observation. Persons within clusters such as communities tend to be more like one another than they are like persons in other communities,[13] and this within-cluster correlation adds an additional component to the variability of the treatment group means over that attributable either to the individual participants or to the treatments.[48] Unless this extra variation is accounted for in analysis, the *P* values for the treatment effects will be artificially deflated.[49] We accounted for the extra variation through a two-stage analysis that approximated a stratified hierarchical analysis of covariance; the nested communities were treated as random effects; condition, time, and stratification factors were treated as fixed effects; and all tests of statistical significance were made at the community level.[50,51]

In the first stage, least-squares adjusted means were generated for each city in each survey year after stratifying simultaneously by gender, educational attainment, and age; adjustments were made for confounding variables specific to each dependent variable by standardizing all subjects to the population average within strata for each covariate. The second stage employed these adjusted strata-specific city-year means as the unit of analysis in a series of regressions to evaluate the main and strata-specific effects of the intervention program as a time-by-treatment interaction. Recognizing that planned contrasts can provide tests that are more interpretable and potentially more powerful, we tested two specific patterns of program effect. For both patterns, a quadratic secular trend was modeled by using the baseline intervention city-year means together with all of the comparison city-year means. The intervention program effect was then modeled first as a series of year-specific departures from that secular trend and second as a linear departure from that trend. The analysis of the cohort data followed the same plan; modifications were made to accommodate time-varying covariates and the fact that different members of the cohort participated in each of the four cohort surveys.

Results

Survey Participation

A total of 20 184 eligible adults age 25–74 years completed the home interview, and 18 062 completed the survey center protocol. Participation rates were stable across all years and communities: enumeration averaged 96.1% of the selected households, home interviews averaged 87.9% of the selected adults, and the total survey response averaged 78.7%.

Of the participants from the baseline cross-sectional surveys, 7097 were randomly selected for the cohort surveys; the refusal rate was 14.9% and the population was relatively stable, with 67.1% of the original group living in the town and participating at the end of the study. The remainder moved or died. Those lost to follow-up were compared with those retained. The ones lost to follow-up had higher smoking rates and lower levels of blood cholesterol, but there was no evidence of differential attrition between the education and comparison sites. The only differences between the education and the comparison communities on loss to follow-up were in body mass index at the 7-year follow-up survey; those lost from the education communities were slightly leaner than those lost from the comparison communities (body mass index of 25.4 vs 25.9).

Exposure to Risk Reduction Activities

Figure 2 summarizes exposure to risk reduction activities, and Table 1 presents the year-specific means for the exposure summary score; only cross-sectional data are presented because the exposure measures were not included in all cohort surveys. The solid line represents the secular trend estimated for exposure based on all nonintervention stratum-specific city-year means and indicates that exposure to these risk reduction activities increased over time in the comparison communities. The dashed line illustrates the Minnesota Heart Health Program effects at 1, 3, 5, and 6 years of intervention. Exposure was significantly higher in the education communities compared with the comparison communities after 1 and 3 years, but not after 5 or 6 years.

Blood Cholesterol Level

Figure 3 and Tables 1 and 2 summarize the findings for blood cholesterol. In the cross-sectional data, the secular trend showed a steady decline in the comparison communities (about −1.12 mg/dL per

year). The mean blood cholesterol was lower in the education communities during the first 3 years of the intervention program and higher in the final 2 years. None of these differences were statistically significant. The cohort findings were similar.

Smoking Prevalence

Figures 4 and 5 and Tables 1 and 2 summarize the findings for cigarette smoking. The response to the intervention program differed by gender, so the figures and tables are gender specific. Among men, there was a downward trend in the comparison communities, both in the cross-section and in the cohort (about −1.5% per year), and there was no added intervention effect. Among women, the secular trend was small in the cross-section, and there was a statistically significant treatment effect (about −1.4% per year) that remained after we corrected the smoking self-report data for underreporting by using serum thiocyanate levels (data not shown). In the cohort, there was a marked decline in smoking prevalence among women and only limited evidence of an intervention effect.

Blood Pressure

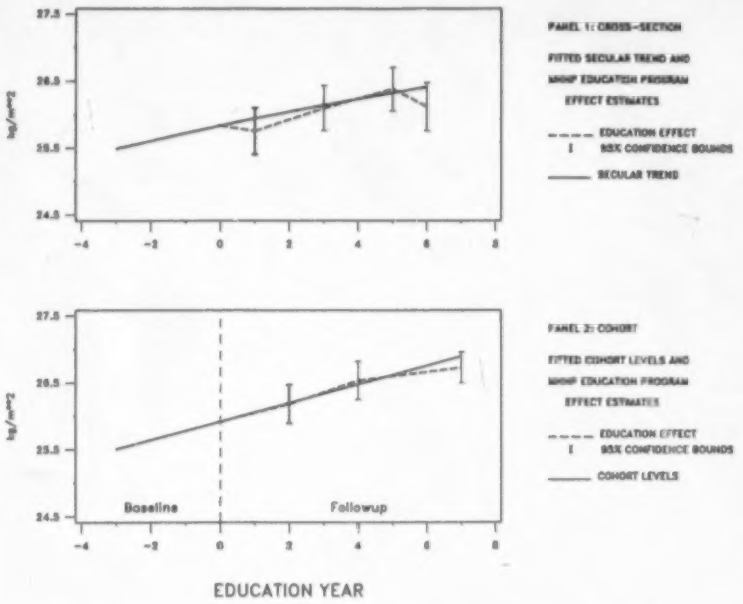
Figures 6 and 7 and Tables 1 and 2 summarize the findings for blood pressure. In the comparison communities, there was evidence of a declining secular trend in the cross-section (averaging −0.4 mm Hg for systolic blood pressure and −0.2 mm Hg for diastolic blood pressure per year) and a flat or slightly rising trend in the cohort, as would be expected with aging. In the education communities, both measures had an additional modest decline after 3 years of intervention in the cross-section and after 2 or 4 years in the cohort; however, none of these changes were statistically significant.

Body Mass Index

Figure 8 and Tables 1 and 2 summarize the findings for body mass index. Both the secular and cohort trends were positive (about +0.1 kg/m^2 per year), and there was no evidence of an intervention effect.

Regular Physical Activity

Figure 9 and Tables 1 and 2 summarize the findings for regular physical activity. The secular trend declined initially but then rose over the last 4 years of the study. The Minnesota Heart Health



Note. Adjusted for age, gender, education, marital status, and seasonal trend. MHHP = Minnesota Heart Health Program.

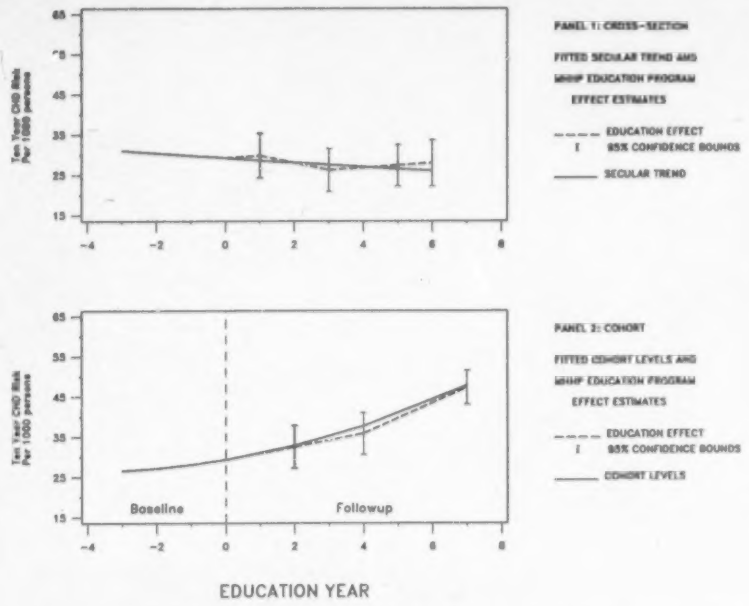
FIGURE 9—Regular physical activity: results of the MHHP education intervention program.



Note. Risk scores were computed by applying the coefficients of Leaverton et al.[20] to the predicted risk factor levels for each participant obtained from the individual risk factor analyses. CHD = coronary heart disease; MHHP = Minnesota Heart Health Program.

FIGURE 10—Coronary heart disease risk score: results of the MHHP education intervention program.

intervention program accelerated this secular trend significantly, especially during the first 3 years of the intervention program. The cohort data suggest a steady increase in self-reported regular physical activity in all communities over the course of follow-up; the education communities exceeded the comparison communities only at the last follow-up survey. We also analyzed the more extensive physical activity data based on the Minnesota Leisure Time Physical Activity Questionnaire, which was answered by a random half of the Minnesota Heart Health Program survey participants. Unlike the findings based on the single question concerning regular participation in leisure time physical activity, results of the longer questionnaire showed a small increase in kilocalories per day expended in leisure time physical activity in the early years of the education program, but a small decrease in later years (data not shown). Time spent in heavier-intensity activities appeared to decrease slightly in the education communities by the end of the program. Resting pulse rate trends (data not shown) reflected the self-reported changes, with lower pulse rates in the education communities associated with higher reported physical activity levels.

Coronary Heart Disease Risk

Figure 10 and Tables 1 and 2 summarize the risk score findings. Risk of death from coronary heart disease declined over time in the cross-section in both the education and the comparison communities, but there was little evidence of an intervention effect. The cohort data reflected increasing risk as the cohort aged, but again, there was little evidence of an intervention effect.

Discussion

The differences observed here between the education and the comparison communities with respect to population-wide risk factor changes were less than postulated. There are several potential explanations for these findings. First, it is apparent that there were strong and favorable secular trends of both increasing health promotion activities and declining risk factors for coronary heart disease in all study communities. Second, it is apparent that the net improvements in health promotion activities and individual risk factors that can be attributed to the Minnesota Heart Health Program intervention were modest, generally of limited duration, and usually within chance levels. In light of the results from previous studies that have supported the efficacy of many of the Minnesota Heart Health Program intervention components in targeted populations, we cannot conclude that those components are ineffective. Instead, we conclude that the Minnesota Heart Health Program intervention was unable to generate enough additional exposure to those risk reduction activities in a large enough proportion of the population to exceed the remarkably favorable secular trends that were ongoing in the study communities. In the next several paragraphs, we review the evidence that led us to this conclusion, consider how these findings compare with the results from similar studies, and consider the implications for public health practice and policy.

Consider first the data on the secular trends for exposure to health promotion activities related to coronary heart disease (Figure 2). Those results suggest that exposure grew steadily in both the comparison and education communities. Examination of the individual items in the exposure score revealed that the net increase in the education communities was attributable largely to higher rates of exposure to cholesterol screening, health projects or surveys, and restaurant menu labeling programs. Other exposure measures showed little difference between the education and the comparison communities. These results suggest that in spite of the Minnesota Heart Health Program's intense intervention program, the increase in such activity over the growing levels observed in the comparison communities was surprisingly limited. This interpretation must be tempered by the limitations inherent in the exposure measures themselves, which assessed whether or not respondents had been exposed to a particular type of risk reduction message or activity and did not discriminate among exposures on the basis of their quality, intensity, or duration. Even so, the exposure data suggest that the Minnesota Heart Health Program may not have added a great deal to the level of risk reduction activity that would have been expected without the program. It may be that the Minnesota Heart Health Program represented too small a fraction of the total exposure to messages related to coronary heart disease to make much difference, or that the Minnesota Heart Health Program supplanted activities that

might otherwise have developed on their own. Either way, the net gain in exposure was modest.

Consistent with the favorable secular trend in exposure to risk reduction messages and activities, the cross-sectional results indicate that there were beneficial and often strong trends for each risk factor, with only two exceptions (smoking in women and body mass index). For example, smoking prevalence declined in men by 11.3%, systolic blood pressure declined by 6.3 mm Hg, and total blood cholesterol declined by 11 mg/dL. The major surprise with regard to these secular trends was their magnitude, because only small changes had been expected in these risk factors when the study was designed in 1978. Instead, the improvements in the secular trends were often much greater than the intervention effects hypothesized for the Minnesota Heart Health Program (e.g., hypothesized effects were for a 3% decline in smoking prevalence, a 7 mg/dL decline in total blood cholesterol, and a 2 mm Hg decline in systolic blood pressure). We note as well that the secular trends were greater than those previously observed nationally in the National Health and Nutrition Examination Survey[52] or regionally in the Minnesota Heart Survey.[53]

The cross-sectional results suggest intervention effects in self-reported smoking prevalence among women and in self-reported physical activity in both men and women; however, the cohort data did not support intervention effects in any of the risk factors. In spite of an extensive effort to explain the difference in smoking outcomes for women between the cross-section and the cohort, no explanation has been found. Because smoking in women was the only risk factor that showed a flat trend over time in the comparison communities, this finding may indicate that the Minnesota Heart Health Program intervention was able to induce a favorable slope in the absence of a favorable secular trend. The increased effect observed toward the end of the study is also consistent with the increased delivery of antismoking messages and activities late in the intervention program. The follow-up analyses for physical activity also suggested that the apparent increase in the proportion of the population who engaged in physical activity in their leisure time was the result of an increase in the proportion who engaged in light activity, not an increase in the proportion who engaged in moderate or vigorous activity. This may explain the absence of a Minnesota Heart Health Program effect on body mass index in spite of the apparent effect on physical activity. Taken together, the risk factor results are consistent with the exposure data and suggest modest variation in coronary heart disease risk factors around their secular trends; the data provide little evidence of any broad or significant acceleration of those secular trends that can be attributed with confidence to the intervention program.

Because data on morbidity and mortality are not yet available, we must look to the coronary heart disease risk score for preliminary evidence of the net effect of the intervention program on the population risk for coronary heart disease (Figure 10). The secular trend in the cross-sectional data is consistent with the trends seen in the exposure and individual risk factor data: the estimated 10-year risk improved by 5.0 predicted deaths per 1000 persons from coronary heart disease over the 9 years of the study. The intervention effect is also consistent with the previous results. As with the risk factors, the improvement in estimated risk due to the secular trend was also larger than the improvement that had been hypothesized for the Minnesota Heart Health Program.

Taken together, the results presented in this paper paint a picture of modest and time-limited improvements in exposure to coronary heart disease risk-reducing messages and activities and in coronary heart disease risk factors, usually within chance levels, with no evidence of any cumulative effect on the estimated risk of dying from coronary heart disease. There are several competing explanations, however, and these should be considered.

One competing explanation is that the intervention components themselves did not work. However, there is extensive published research from this study and others demonstrating the efficacy of many of those risk reduction strategies, so this alternative is simply not plausible.[25–47] A second explanation is that the intervention program may have focused on the wrong population segments or used the wrong mix of intervention components. The exposure data suggest that the Minnesota Heart Health Program succeeded in distributing its programs and activities evenly across the strata defined by age, gender, and educational attainment, consistent with the population-based approach of the study, and we cannot know whether the program might have been more effective had it been focused on a particular population segment. In terms of program components, the Minnesota Heart Health Program relied on mass media channels to achieve its awareness goals and on face-to-face direct education activities and communitywide events to achieve its goals for behavior change.[54] Unlike today, there was little support when the Minnesota Heart Health Program was conceived in 1978 for policy-level interventions such as restrictions on smoking and more accurate labeling of food products. Although politically more difficult, these interventions may prove to be more effective than the traditional health education strategies of the 1980s, and it may be that a community program built around a combination of public policy initiatives and the more traditional health education strategies could be more effective. A third alternative explanation is that the Minnesota Heart Health Program's working definition of the community may have been too narrow. The Minnesota program attempted to change the health behaviors and risk behaviors of the residents of three specific communities, with no effort or ability to control or change the broader social milieu in which those communities existed. Just as we have learned that it is difficult to change the behavior of individuals without changing the communities in which they live, we may be learning that it is difficult to change the behavior of whole communities without changing their broader social environment as well. A fourth and final alternative explanation is that health promotion activities such as those developed and implemented in the education communities spread rapidly in the region and effectively "contaminated" the comparison communities. The exposure data presented in Figure 2 provide support for this alternative.

The results from the Minnesota Heart Health Program can be compared with those reported by the Stanford Three- and Five-Community Studies and the North Karelia Study. They also observed modest and often variable improvements in coronary heart disease risk factors after a period of communitywide intervention. In the North Karelia Study,[11] improvements in the intervention community were substantial, but similar trends occurred in the comparison area. In the Stanford Five-Community Project, where the secular trends were not as strong, the risk factor changes were larger and frequently significant.[9] Findings in the Stanford Three- and Five-Community Projects were less frequently significant in analyses

conducted at the city-year level, as we have done in this paper; even so, significant intervention effects remained for some outcomes, including their coronary heart disease risk score.[9,12]

Given the general consistency of the Minnesota Heart Health Program results, it is important to consider the implications of these findings for public health practice and public policy. It is tempting to interpret these results as indicating that the intensive communitywide cardiovascular risk reduction program was ineffective, but that would be an oversimplification. Many of the individual components of the Minnesota Heart Health Program intervention have been shown to be effective in earlier studies. Those components, such as risk factor screening and education, classes for smoking cessation, and dietary change, are still recommended for use by individuals, groups, and communities. What we now recognize is that it is far easier to change the risk profiles of the people who participate in those programs than to engage a large enough fraction of the community to change risk profiles of the entire community. □

Acknowledgments

This research was supported by a grant from the National Heart, Lung and Blood Institute (R01 HL 25523).

The authors wish to thank the staff, students, and volunteers who worked on the Minnesota Heart Health Program. Particular thanks to the citizens and leadership of Mankato, Minn; Fargo, ND; Moorhead, Minn; and Bloomington, Minn. We also wish to recognize F. Gerald Kline, PhD (deceased), and Henry L. Taylor, PhD (deceased), for their many contributions. Finally, we wish to thank the members of the MHHP Scientific Advisory Board for their guidance throughout the study: Thomas Cook, PhD, Northwestern University; Leslie Kish, PhD, University of Michigan; John W. Farquhar, MD, Stanford University; Lawrence W. Green, DrPH, University of British Columbia; Lester Breslow, MD, MPH, University of California at Los Angeles; Kenneth J. Rothman, DrPH, EPI Resources; and Lee Stauffer, PhD, MPH, University of Minnesota.

How Effective Is Drug Abuse Resistance Education? A Meta-Analysis of Project DARE Outcome Evaluations

Susan T. Ennett, PhD, Nancy S. Tobler, MS, PhD, Christopher L. Ringwalt, DrPH, and Robert L. Flewelling, PhD

ABSTRACT

Objectives. Project DARE (Drug Abuse Resistance Education) is the most widely used school-based drug use prevention program in the United States, but the findings of rigorous evaluations of its effectiveness have not been considered collectively.

Methods. We used meta-analytic techniques to review eight methodologically rigorous DARE evaluations. Weighted effect size means for several short-term outcomes also were compared with means reported for other drug use prevention programs.

Results. The DARE effect size for drug use behavior ranged from .00 to .11 across the eight studies; the weighted mean for drug use across studies was .06. For all outcomes considered, the DARE effect size means were substantially smaller than those of programs emphasizing social and general competencies and using interactive teaching strategies.

Conclusions. DARE's short-term effectiveness for reducing or preventing drug use behavior is small and is less than for interactive prevention programs. (*Am J Public Health.* 1994;84:1394–1401)

Introduction

School-based drug use prevention programs have been an integral part of the US antidrug campaign for the past two decades.[1,2] Although programs have proliferated, none is more prevalent than Project DARE (Drug Abuse Resistance Education).[3] Created in 1983 by the Los Angeles Police Department and the Los Angeles Unified School District, DARE uses specially trained law enforcement officers to teach a drug use prevention curriculum in elementary schools[4] and, more recently, in junior and senior high schools. Since its inception, DARE has been adopted by approximately 50% of local school districts nationwide, and it continues to spread rapidly.[3] DARE is the only drug use prevention program specifically named in the 1986 Drug-Free Schools and Communities Act. Some 10% of the Drug-Free Schools and Communities Act governors' funds, which are 30% of the funds available each fiscal year for state and local programs, are set aside for programs "such as Project Drug Abuse Resistance Education,"[5] amounting to much of the program's public funding.

Given its widespread use and the considerable investment of government dollars, school time, and law enforcement effort, it is important to know whether DARE is an effective drug use prevention program. That is, to what extent does DARE meet its curriculum objectives, most prominently "to keep kids off drugs"?

DARE's core curriculum, offered to pupils in the last grades of elementary school, is the heart of DARE's program and the focus of this study. We evaluate here the core curriculum's short-term effectiveness by using meta-analytic techniques to integrate the evaluation findings of several studies.[6,7] We searched for all DARE evaluations, both published and unpublished, conducted over the past 10 years and selected for further review those studies that met specified methodological criteria. We calculated effect sizes as a method for establishing a comparable effectiveness measure across studies.[7–9] In addition, to put DARE in the context of other school-based drug use prevention programs, we compared the average magnitude of the DARE effect sizes with those of other programs that target young people of a similar age.

DARE's Core Curriculum

The DARE core curriculum's 17 lessons, usually offered once a week for 45 to 60 minutes, focus on teaching pupils the skills needed to recognize and resist social pressures to use drugs.[4] In addition, lessons focus on providing information about drugs, teaching decision-making skills, building self-esteem, and choosing healthy alternatives to drug use.[4] DARE officers use teaching strategies, such as lectures, group discussions, question-and-

answer sessions, audiovisual material, workbook exercises, and role-playing.[4]

The training that DARE officers receive is substantial. They are required to undergo 80 training hours in classroom management, teaching strategies, communication skills, adolescent development, drug information, and curriculum instruction.[4] In addition, DARE officers with classroom experience can undergo further training to qualify as instructors/mentors.[4] These officers monitor the program delivery's integrity and consistency through periodic classroom visits.

Methods

Identification of Evaluations

We attempted to locate all quantitative evaluations of DARE's core curriculum through a survey of DARE's five Regional Training Centers, computerized searches of the published and unpublished literature, and telephone interviews with individuals known to be involved with DARE. Eighteen evaluations in 12 states and one province in Canada were identified. Several evaluations were reported in multiple reports or papers. (See Appendix A for a bibliography of the studies considered.)

Evaluation Selection Criteria

To be selected for this meta-analysis, an evaluation must have met the following criteria: (1) use of a control or comparison group; (2) pretest-posttest design or posttest only with random assignment; and (3) use of reliably operationalized quantitative outcome measures. Quasi-experimental studies were excluded if they did not control for preexisting differences on measured outcomes with either change scores or covariance-adjusted means.[10] In addition, to ensure comparability, we focused on results based only on immediate posttest. Because only four evaluation studies were long term (two of which were compromised by severe control group attrition or contamination), we were unable to adequately assess longer-term DARE effects.

We examined several other methodological features, such as the correspondence between the unit of assignment and analysis, the use of a panel design, matching of schools in the intervention and control conditions, and attrition rates. Although these factors were considered in assessing the studies' overall methodological rigor, we did not eliminate evaluations on the basis of these criteria.

Data Analysis

For each study, we calculated an effect size to quantify the magnitude of DARE's effectiveness with respect to each of six outcomes that reflect the DARE curriculum's aims. An effect size is defined as the difference between the intervention and the control group means for each outcome measure, standardized by dividing by the pooled standard deviation [effect size = $\text{mean}_I - \text{mean}_C$/SD].[7-9] If means and standard deviations were not available, we calculated effect sizes using formulas developed to convert other test statistics and percentages to effect sizes.[9] In all cases, we used statistics reflecting covariance-adjusted means, with pretest values as covariates rather than unadjusted means so that any differences between the comparison groups before the intervention would not be reflected in the effect sizes.[10]

The six outcome measure classes include knowledge about drugs, attitudes about drug use, social skills, self-esteem, attitude toward police, and drug use. Some studies did not include all six, and some outcomes were measured by more than one indicator. When multiple indicators were used (e.g., two measures of social skills), we calculated separate effect sizes and then averaged them.[6,10] This procedure yielded one effect size per study for each measured outcome type. In the one study that reported only that a measured outcome was not statistically significant (and did not provide any further statistics), we assigned a zero value to that effect size.[10] To calculate effect sizes for drug use, we considered only alcohol, tobacco, and marijuana use; we averaged effect sizes across these substances. In a supplementary analysis, we considered use of these substances separately. The prevalence of other drugs, such as cocaine, was too small to produce meaningful effects.

In addition to calculating one effect size per outcome per study, we calculated the weighted mean effect size and 95% confidence interval (CI) for each outcome type across programs. The weighted mean is computed by weighting each effect size by the inverse of its variance, which is a reflection of the sample size.[8,9] The effect size estimates from larger studies are generally more precise than those from smaller studies.[8] Hence, the weighted mean provides a less biased estimate than the simple, unweighted mean because estimates from larger samples are given more weight. The 95% CI indicates the estimated effect size's accuracy or reliability and is calculated by adding to or subtracting from the mean 1.96 multiplied by the square root of 1 divided by the sum of the study weights.[8]

Comparison of DARE with Other Drug Use Prevention Programs

For comparison with DARE, we used the effect sizes reported in Tobler's meta-analysis of school-based drug use prevention programs.[10] To allow the most appropriate comparisons with DARE effect sizes, we obtained Tobler's results for only those programs (excluding DARE) aimed at upper elementary school pupils. These programs are a subset of 25 from the 114 programs in Tobler's meta-analysis, whose studies are referenced in Appendix B.

We selected this meta-analysis for comparison because of its greater similarity to ours than other meta-analyses of drug use prevention programs.[11-14] Tobler's studies met the same methodological standards that we used for the DARE studies. The only differences were that Tobler excluded studies that did not measure drug use and considered results from later posttests, whereas we considered only immediate posttest results. Neither of these differences, however, should seriously compromise the comparison.

The evaluation studies included in Tobler's meta-analysis are classified into

two broad categories based on the programs' content and process. Process describes the teaching approach (how the content is delivered). Programs classified by Tobler as "noninteractive" emphasize intrapersonal factors, such as knowledge gain and affective growth, and are primarily delivered by an expert. "Interactive" programs emphasize interpersonal factors by focusing on social skills and general social competencies and by using interactive teaching strategies, particularly peer to peer. Consistent with other meta-analyses showing that programs emphasizing social skills tend to be the most successful,[11–13,15] interactive programs produced larger effect sizes than noninteractive programs. We compared DARE with both categories of programs.

Results

Characteristics of Evaluations

Of the original 18 studies, 8 met the criteria for inclusion. One additional study met the methodological criteria but did not administer the first posttest until 1 year after DARE implementation; therefore, it could not be included in our analysis of immediate effects.[16,17] The location and primary reference for each evaluation are shown in Table 1, and study characteristics are summarized in Table 2.

Each evaluation represents a state or local effort. The number of student subjects in all studies was large, each study comprising at least 10 schools with approximately 500 to 2000 students. Although demographic information was not given for three studies, the remaining five studies in the sample primarily consisted of White subjects.

Assignment of DARE to intervention and control groups was by school for all eight studies. In one study, DARE also was assigned by classroom in certain schools.[18] Because of potential contamination in this study of the control group classrooms by their close proximity to DARE classes, we eliminated these control classrooms; only control schools with no DARE classes were included. Two studies used a true experimental design in which schools were randomly assigned to DARE and control conditions; a third study used random assignment for two thirds of the schools. The remaining five evaluations used a nonequivalent control group quasi-experimental design.

Because there were relatively few sampling units across studies—ranging from 11 to 63 schools, with all except one study involving fewer than 40 schools—it is unlikely that equivalence between

groups was obtained without prior matching or blocking of schools, even with randomization. Only half the studies matched comparison schools on selected demographic characteristics. Most studies (75%), however, assessed the equivalency of the comparison groups at pretest and made adjustments for pretest differences on demographic characteristics. All studies adjusted for pretest differences on outcome measures.

All but one study used a panel design that matched subjects from pretest to posttest with a unique identification code.

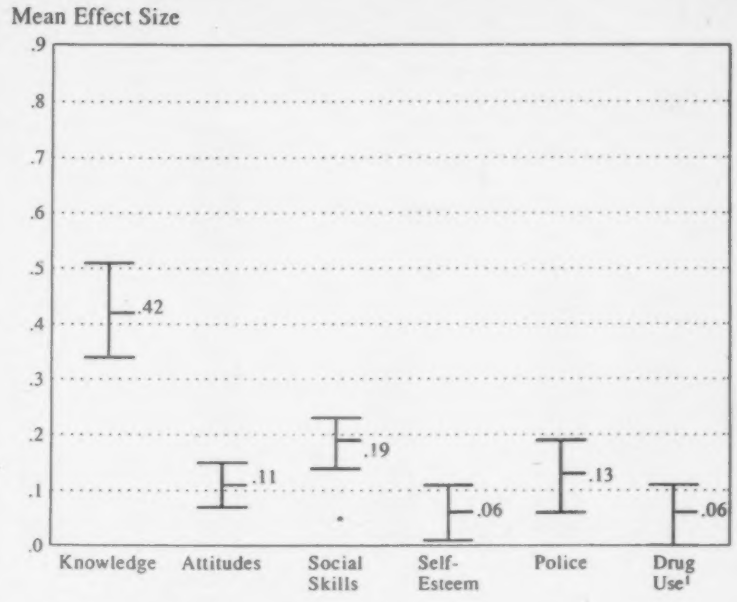
Outcome measures used in the DARE evaluations were based on responses to self-administered questionnaires. Seven studies used standardized scales or revised existing measures; six studies reported generally high scale reliabilities (usually Cronbach's alpha). Validity information, however, was rarely reported, and no study used either a biochemical indicator or "bogus pipeline" technique to validate drug use self-reports.[19]

Most studies (75%) did not use a data analysis strategy appropriate to the unit of assignment. Because schools, not students, were assigned to DARE and control conditions, it would have been appropriate to analyze the data by schools with subjects' data aggregated within each school or to use a hierarchical analysis strategy in which subjects are nested within schools.[20,21] Six studies ignored schools altogether and analyzed individual subjects' data, thereby violating the statistical assumption of independence of observations. Ignoring schools as a unit of analysis results in a positive bias toward finding statistically significant program effects.[21] This bias may be reflected in CIs reported for each outcome's weighted mean effect size.

Five studies reported generally small attrition rates. None of the three studies that analyzed attrition found that rates differed significantly across experimental and control conditions. In addition, subjects absent from the posttest were not more likely to be drug users or at risk for drug use. Although attrition usually is greater among drug users,[22] given the sample's young age (when school dropout is unlikely and drug use prevalence is low), these results are not surprising.

DARE Effect Sizes

Study effect sizes are shown in Table 3. In general, the largest effect sizes are for knowledge and social skills; the smallest are for drug use.



[1]Drug use includes alcohol, tobacco, and marijuana.

FIGURE 1—Magnitude of DARE's weighted mean effect size (and 95% CI), by outcome measure.

Figure 1 shows the mean weighted effect size and 95% CI for each outcome based on the eight studies combined. The largest mean effect size is for knowledge (.42), followed by social skills (.19), attitude toward the police (.13), attitudes about drug use (.11), self-esteem (.06), and drug behavior (.06). The effect sizes for knowledge, social skills, attitude toward the police, attitudes about drug use, and self-esteem are statistically significant. The CI for the mean drug use effect size overlaps with zero (i.e., it is not significantly different from zero).

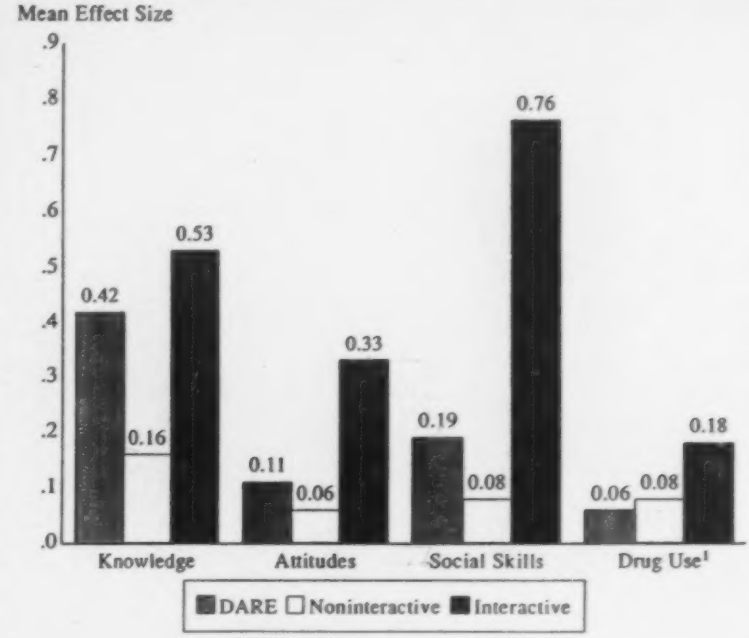
Because averaging alcohol, tobacco, and marijuana use for the drug use effect size could obscure substantial differences among the substances, we calculated DARE's mean weighted effect sizes separately for these substances. The weighted mean effect size for alcohol use is .06 (95% CI = .00, .12); for tobacco use, .08 (95% CI = .02, .14); and for marijuana use, −.01 (95% CI = −.09, .07). Only the mean for tobacco use is statistically significant.

Mean Effect Sizes for DARE vs Other Drug Use Prevention Programs

We compared by type of outcome the mean weighted DARE effect size with the mean weighted effect size for noninteractive (n = 9) and interactive (n = 16) programs; effect sizes for the comparison programs are derived from Tobler.[10] The comparison programs target youth of the same grade range targeted by DARE. The outcomes assessed by both DARE and the comparison programs are knowledge, attitudes, social skills, and drug use behavior.

Across the four outcome domains, DARE's effect sizes are smaller than those for interactive programs (Figure 2). Most notable are DARE's effect sizes for drug use and social skills; neither effect size (.06 and .19, respectively) is more than a third of the comparable effect sizes for interactive programs (.18 and .75, respectively). DARE's effect size for drug use is only slightly smaller than the noninteractive programs' effect size. DARE's effect sizes for knowledge, attitudes, and social skills, however, are larger than those for noninteractive programs.

Comparison of effect sizes separately for alcohol, tobacco, and marijuana use shows that DARE's effect sizes are smaller than those for interactive programs (Figure 3). Except for tobacco use,



Note. Comparison programs selected from Tobler.[10]
[1]Drug use includes alcohol, tobacco, and marijuana.

FIGURE 2— Weighted mean effect size, by outcome, for DARE and other drug use prevention programs.

they also are smaller than those for noninteractive programs.

Discussion

The results of this meta-analysis suggest that DARE's core curriculum effect on drug use relative to whatever drug education (if any) was offered in the control schools is slight and, except for tobacco use, is not statistically significant. Across the studies, none of the average drug use effect sizes exceeded .11. Review of several meta-analyses of adolescent drug use prevention programs suggests that effect sizes of this magnitude are small.[10–14]

The small magnitude of DARE's effectiveness on drug use behavior may partially reflect the relatively low frequency of drug use by the elementary school pupils targeted by DARE's core curriculum. However, comparison of the DARE effect sizes with those of other school-based drug use prevention programs for same-age adolescents suggests that greater effectiveness is possible with early adolescents. Compared with the programs classified by Tobler as interactive, DARE's effect sizes for alcohol, tobacco, and marijuana use, both collectively and individually, are substantially less.[10] Except for tobacco use, they also are less than the drug use effect sizes for more traditional, noninteractive programs.

It has been suggested that DARE may have delayed effects on drug use behavior once pupils reach higher grades.[23,24] Longer-term follow-up studies are needed to test this possibility. Only four reviewed studies administered multiple posttests, and for two of these the results from some later posttests are uninterpretable. However, based on two experimental studies for which reliable information 1 and 2 years after implementation is available, there is no evidence that DARE's effects are activated when subjects are older.[25,26] Most long-term evaluations of drug use prevention programs have shown that curriculum effects decay rather than appear or increase with time.[27,28]

DARE's immediate effects on outcomes other than drug use were somewhat larger (especially for knowledge) and were statistically significant. These effect sizes, however, also were less than the comparable effect sizes for same-age interactive programs. That DARE's effect sizes for knowledge, attitudes, and skills were greater in magnitude than those of noninteractive programs may not be particularly meaningful because many of these types of programs, such as programs using "scare tactics" or emphasizing factual knowledge about drug use, have been discredited as unsuccessful.[29,30]

Comparison of DARE's core curriculum content with the interactive and noninteractive programs' curricula may partially explain the relative differences in effect sizes among these programs. Interactive programs tend to emphasize developing drug-specific social skills and more general social competencies, whereas noninteractive programs focus largely on intrapersonal factors. Because DARE has features of both interactive and noninteractive programs, it is perhaps not surprising that the effect sizes we reported should fall somewhere in between. Perhaps greater emphasis in the DARE core curriculum on social competencies and less emphasis on affective factors might result in effect sizes nearer to those reported for interactive programs. However, it is difficult to speculate on the effect of adding or subtracting particular lessons to or from DARE's curriculum. Most school-based prevention program evaluations have assessed the effectiveness of an overall program rather than various program components or combinations of components.

Who teaches DARE and how it is taught may provide other possible explanations for DARE's limited effectiveness. Despite the extensive DARE training received by law enforcement officers, they may not be as well equipped to lead the curriculum as teachers. No studies have been reported in which the DARE curriculum was offered by anyone other than a police officer; results from such a study might suggest whether teachers produce better (or worse) outcomes among pupils.

Regardless of curriculum leader, however, the generally more traditional teaching style used by DARE has not been shown to be as effective as an interactive teaching mode.[10,14] Although some activities encourage pupil interaction, the curriculum relies heavily on the officer as expert and makes frequent use of lectures and question-and-answer sessions between the officer and pupils. In fact, it is in teaching style, not curriculum content, that DARE most differs from the interactive programs examined by Tobler.

The DARE core curriculum recently was modified to introduce more participatory activities, which may lead to greater program effectiveness.

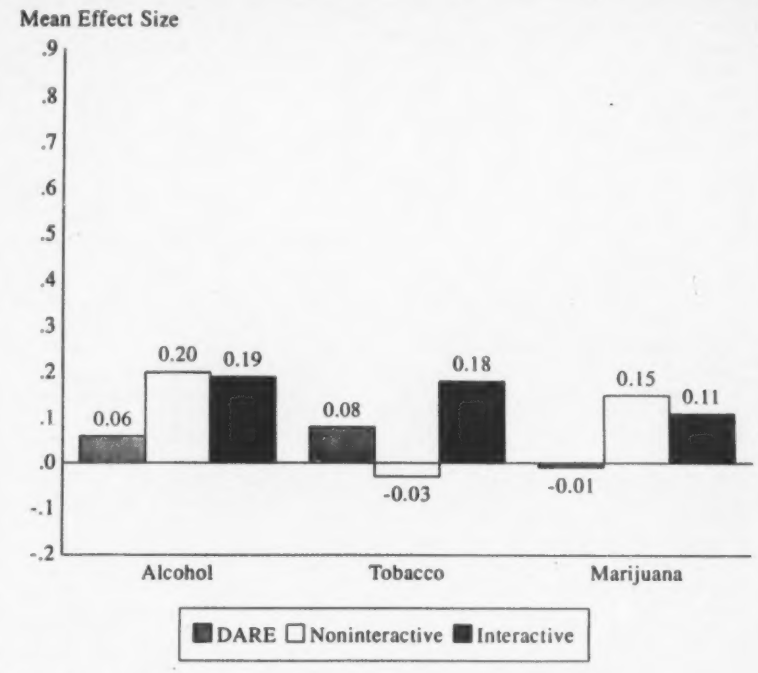
Several limitations should be considered in evaluating our findings. The number of evaluations reviewed (eight) is not large when compared with the vast number of sites where DARE has been implemented. The consistency of results across studies, however, suggests that the results are likely to be representative of DARE's core curriculum. Even so, we would have preferred a full set of eight effect sizes for each outcome.

It is possible that the effect sizes for the DARE studies may have been attenuated compared with the drug use prevention programs reviewed by Tobler because the control groups were not pure "no treatment" groups. As documented by Tobler, effect sizes are lower when the control group receives some sort of drug education.[10,14] The DARE evaluations generally lacked information on alternative treatments received by the control groups, but it is likely that most control groups received some drug education because the studies occurred after the 1986 Drug-Free Schools and Communities Act. However, approximately half (54%) of the programs reviewed by Tobler also were conducted between 1986 and 1990, suggesting that they may suffer from the same effect.[10]

Most of the drug use prevention programs evaluated by Tobler were university research-based evaluation studies, whereas DARE is a commercially available curriculum. Although the magnitude of the resources invested in DARE is considerable, the intensity of effort devoted to smaller-scale programs may be greater. Some diminished effectiveness is perhaps inevitable once programs are widely marketed.

Although we found limited immediate core curriculum effects, some features of DARE may be more effective, such as the middle school curriculum. In addition, DARE's cumulative effects may be greater in school districts where all DARE curricula for younger and older students are in place. Other DARE outcomes, such as its impact on community law enforcement relations, also may yield important benefits. However, due to the absence of evaluation studies, consideration of these features is beyond this study's scope.

DARE's limited influence on adolescent drug use behavior contrasts with the program's popularity and prevalence. An important implication is that DARE could be taking the place of other, more beneficial drug use curricula that adolescents could be receiving. At the same time, expectations concerning the effectiveness of any school-based curriculum, including DARE, in changing adolescent drug use behavior should not be overstated.[31] □



Note. Comparison programs selected from Tobler.[10]

Drinking Behavior in Relation to Cause of Death among US Adults

ABSTRACT

Objectives. Alcohol involvement is common in many fatal injuries. This study examines drinking behavior in a nationally representative sample of US adult decedents aged 25 through 64 years and its association with cause of death.

Methods. Proxy-reported information from the 1986 National Mortality Followback Survey was used to profile the decedents' usual frequency and quantity of drinking. The association of drinking behavior with underlying cause of death was assessed while adjusting for demographic characteristics.

Results. Of the decedents, 17% were daily drinkers, 22% usually consumed five drinks or more per occasion, and 27% were classified as heavier drinkers. Persons who died of injury drank more frequently and heavily than those who died of disease. The adjusted odds ratio of injury's being the underlying cause of death was 1.4 (95% confidence interval [CI] = 1.1, 1.8) for daily drinkers, 1.5 (95% CI = 1.1, 2.0) for those drinking five or more drinks per occasion, and 1.4 (95% CI = 1.1, 1.7) for heavier drinkers.

Conclusions. Daily drinking, binge drinking, and heavier drinking were each associated with an increased likelihood of injury as the underlying cause of death. Persons who were young, male, Native American, or divorced or separated were more likely to drink frequently and heavily. (*Am J Public Health.* 1994;84: 1402–1406)

Introduction

The high involvement rate of alcohol use in fatal injuries is well documented.[1–12] For example, blood alcohol has been found in about 40% to 60% of motor vehicle crash victims,[1,4,5] 32% to 46% of homicide victims,[4,6] 20% to 50% of suicides,[4,7] 25% to 30% of drowning victims,[8,9] and 40% to 64% of fire and burn fatalities.[4,10,11] Although alcohol use is generally considered one of the most important risk factors for almost all injuries, the causal role of alcohol use in injuries, except in motor vehicle injury, is largely unproven.[9,12] Several studies have suggested that only heavy drinking is associated with a significantly increased risk of injury.[13,14] One of the studies found a strong association with the number of drinks per occasion but little association with average weekly consumption.[13]

Although alcohol use is directly related to some diseases (e.g., cirrhosis of the liver), the effects of alcohol use on total mortality and coronary heart disease appear to form a U-shaped curve, with the lowest mortality among moderate drinkers and increased mortality among abstainers and heavy drinkers. The public health implications of these findings, however, are not clear because of concerns over other harmful effects of increased alcohol consumption.[15–17]

Most studies relating alcohol to injury or disease have been conducted in limited, select population groups. The purposes of this study were to examine the drinking patterns of a nationally representative sample of US adults aged 25 through 64 years who died in 1986 and the relationship between drinking behavior and the underlying cause of death.

Methods

Data for this study were from the 1986 National Mortality Followback Survey conducted by the National Center for Health Statistics. This survey was designed to collect information on characteristics of decedents that may have affected mortality but were not available on the death certificates. About 1% (18 733) of all adults aged 25 years or older who died in 1986 in the United States, excluding the state of Oregon, were included in this survey, which was based on a stratified random sampling strategy. Information on decedents was obtained by mail questionnaire, telephone, or personal interview from the informants named on the death certificates. The overall response rate was 89%.[18]

Three questions from the survey were used for this analysis. First, a screening question was asked to separate drinkers from nondrinkers: "In his/her entire adult life, did he/she have at least 12 drinks of any kind of alcoholic beverage, such as beer, wine, or liquor?" On frequency of drinking: "On the average, during adult life, how often did he/she drink any alcoholic beverages, such as beer, wine, or liquor?" Finally, consumption per occasion: "On the days that he/she drank, how many drinks did he/she have on the average, per day?" These questions were especially designed to collect information about usual prac-

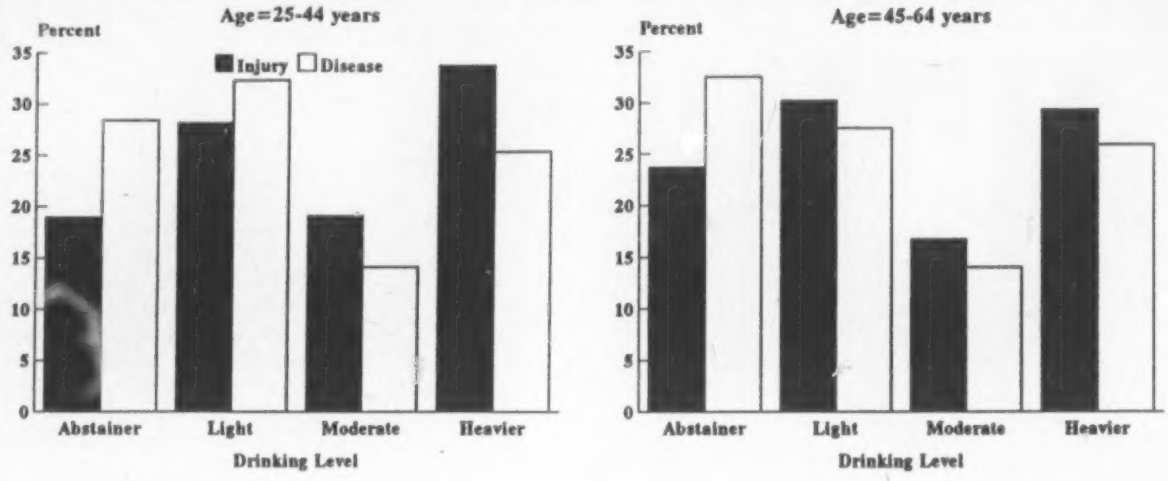

FIGURE 1—Percentage distribution of drinking levels, by decedents' age and cause of death, National Mortality Followback Survey, 1986.

tice rather than any recent change in drinking because of illness.

Excluded from this study were 2135 persons lost to followback, 1872 persons for whom information on any of the three questions was missing, 8173 persons aged 65 or older, and 198 persons whose underlying cause of death was chronic liver disease and cirrhosis (International Classification of Diseases, Ninth Revision[19] [ICD-9] code 571). Persons who died at age 65 or older were excluded because of the difficulty of selecting a single underlying cause of death and the substantial underreporting of injury as the underlying cause of death in the elderly.[20,21] Persons whose underlying cause of death was chronic liver disease or cirrhosis were excluded because alcohol use is very highly correlated with these diagnoses.[22] Thus, the sample size available for data analysis was 6355. Persons who were excluded from this study because their proxies failed to respond or because information on their alcohol use was missing were similar to the sample in age, race, and education but were more likely to be male and unmarried.

Drinking behavior was measured by usual frequency of drinking, usual number of drinks per occasion, and drinking level. Drinking level was determined by the well-established quantity-frequency method, using standard categories[22]: an abstainer was defined as a person who drank fewer than 12 drinks per year; a light drinker, one who drank up to 3 drinks per week; a moderate drinker, one who drank 4 to 13 drinks per week; and a heavier drinker, one who drank 14 drinks or more per week. A standard drink was defined as about 15 g of ethanol.

The underlying cause of death was divided into disease (ICD-9 codes 001–799) and injury (ICD-9 codes E800–E999). Multivariate logistic regression was used to evaluate the effects of drinking behavior on the cause of death while adjusting for demographic characteristics.

Results

The study sample included 5075 persons who died of disease and 1280 who died of injury. Those who died of injury were significantly younger and were more likely to be male, White, Native American, divorced, separated, or never married than persons who died from disease ($P < .01$).

Frequency of Drinking

About 17% of all decedents never drank, and 51% drank at least once a week. Those who died of disease were more likely to be nondrinkers than were those who died of injury (18% vs 12%, $P < .01$). About 40% of those who died of disease either never drank or were infrequent drinkers (less than once per month), compared with 26% for those who died of injury. In contrast, those who died of injury were more likely to be daily drinkers or frequent drinkers (at least once a week) than were those who died of disease, in both sexes and all age groups.

The frequency of drinking differed greatly by sex. Among men, 11% never drank and 62% drank at least once a week, compared with 26% and 33%, respectively, among women. White decedents were most likely to be infrequent drinkers (21%) and Native Americans had the highest rate of daily drinking (23%). Divorced and separated decedents were the most likely of all marital status groups to drink daily (25% for both groups, compared with 15% for married decedents; $P < .01$).

Number of Drinks per Occasion

Overall, 41% of the study sample usually consumed three or more drinks per occasion, and 22% usually consumed five or more drinks per occasion. The prevalence of binge drinking (i.e., five drinks or more per occasion) for those who died of injury was 1.4 times that of persons who died of disease (29% vs 21%, $P < .01$).

The prevalence of binge drinking varied little by age. Male decedents were 2.4 times as likely as female decedents to be binge drinkers (29% vs 12%, $P < .01$). Native American decedents drank much more heavily than members of other races; 50% of the Native American decedents usually consumed five or more drinks per occasion, compared with 21%

TABLE 1—Percentage Distribution of Drinking Levels of Decedents, by Demographic Characteristics: National Mortality Followback Survey, 1986

	Abstainer	Light Drinker	Moderate Drinker	Heavier Drinker
Age at death, y				
25–34	23.2	31.2	18.1	27.5
35–44	26.5	30.6	14.2	28.7
45–54	30.9	28.6	15.0	25.5
55–64	32.9	26.9	13.4	26.8
Sex				
Male	19.7	27.1	17.9	35.3
Female	42.8	32.5	10.4	14.3
Race				
White	28.2	31.0	14.9	25.9
Black	29.9	25.3	15.5	29.3
Native American	18.7	22.2	18.2	40.9
Other	46.4	24.6	5.8	23.2
Education, y				
<12	27.4	24.5	15.7	32.3
12	29.9	31.0	13.5	25.6
13–15	26.6	34.3	16.0	23.1
≥16	27.7	34.5	16.3	21.5
Marital status				
Married	29.3	33.1	15.3	22.3
Widowed	39.2	24.8	9.4	26.6
Divorced	21.1	23.9	15.4	39.6
Separated	24.2	22.8	13.6	39.4
Never married	30.7	26.0	15.8	27.5

Note. All percentages are row percentages.

of the White decedents and 23% of the Black decedents ($P < .01$). Decedents with less than 12 years of education were 2.7 times as likely as decedents with more than 15 years of education to be binge drinkers. The highest prevalence rate of binge drinking was among decedents who were divorced or separated (34%), followed by those who had never been married (22%), those who were married (18%), and those who were widowed (17%).

Drinking Level

The prevalence of heavier drinking in the study sample was 27%. About a third of those who died of injury (33%) were heavier drinkers, compared with a quarter of those who died of disease ($P < .01$). The association of drinking behavior with cause of death was more striking among young adults than among older adult decedents (Figure 1).

Drinking patterns were similar among the major categories of disease and among the major categories of injury (Figure 2). As found earlier, drinking levels were higher in the injury groups.

High rates of heavier drinking were found among men, Native Americans, persons with less than 12 years of education, and the divorced or separated. The prevalence of heavier drinking was fairly stable over age (Table 1).

Logistic Regression Models

Usual frequency of drinking, number of drinks per occasion, and drinking level were consistently associated with an elevated risk of injury as the underlying cause of death, and each appeared to have a dose–response effect (Table 2). However, the adjusted odds ratios were much smaller than the corresponding crude odds ratios. The effects of demographic variables were similar in the three models. The most important determinant of cause of death was age: the younger the decedent, the more likely it was that the cause of death was injury.

Discussion

This study revealed that 58% of decedents aged 25 through 64 years were either abstainers or light drinkers, and more than a quarter (27%) were heavier drinkers. About 17% of the decedents drank daily, and 22% of all decedents usually consumed five drinks or more per occasion. Drinking patterns across demographic characteristics were consistent with the findings from the 1984 National Alcohol Survey.[23] In both the general population and the decedents, it appeared that the young, Native Americans, and divorced or separated persons were more likely to drink frequently and heavily. Unfortunately, the National Mortality

Followback Survey did not collect information on adults younger than 25 years, a high-risk group for alcohol involvement. Because demographic characteristics were also related to the cause of death, they were strong confounding variables when we examined the effect of drinking behavior on the cause of death. This was illustrated by the discrepancy between the crude odds ratios and the adjusted odds ratios. When adjustments were made for these demographic variables, the association of drinking behavior with the underlying cause of death was weakened, but it was still statistically significant.

The information on drinking behavior was based on responses from proxies, who were primarily the decedents' next of kin. Many studies have assessed the agreement between self- and proxy-reported information on drinking and drinking problems.[24,25] No consensus has emerged about the validity of proxy-reported drinking problems. However, for information on "usual" frequency and quantity of alcohol use, that is, the type of information that this study used, the concordance between self-reports and proxy reports is quite high (60%–70%).[24] Even though informants were explicitly instructed that information on the decedent was about usual practice (i.e., before the decedent became acutely ill), drinking behavior could be more likely to be underreported for persons who died of disease than for those who died of injury because patients with chronic conditions tend to reduce their drinking. Such underreporting would lead to somewhat overestimated odds ratios.

It is noteworthy that we could not determine the association of drinking behavior with the risk of fatal injury or other causes of death because our comparison group was not a representative sample of the general population. Previous studies of alcohol use and the risk of nonfatal injury in which diseased persons were used as a comparison group reported contradictory results. Two cohort studies reported that alcohol use was not associated with a significantly increased risk of fatal injury.[26,27] Other studies have found that an increased risk of fatal injury was associated with the quantity of alcohol consumed (number of drinks per occasion),[13,28] recent history of being drunk,[29] and the frequency of hangover.[30]

Drinking level based on the quantity-frequency method, although typically used to study the adverse health consequences of alcohol use, may be less reliable for estimating injury risk. Regular consumption of 2 or 3 drinks per day places a person in the heavier drinking category, yet the person may never achieve a blood alcohol concentration that would increase the risk of injury. On the other hand, an infrequent binge drinker could be categorized as a light drinker according to the quantity-frequency method, but on occasion such a person would achieve a high blood alcohol concentration and be at high risk of injury. Such a relationship was suggested by Anda et al.,[13] who found the risk of fatal injury to be related to quantity of alcohol consumed per occasion but not total consumption over a 1-month period.

Drinking and injury could interact in two ways. First, the increased risk of injury may result from drinking behavior that exposes the subject to more hazardous circumstances, for example, drinking in bars where the risk of assault is high or driving at excessive speed. Second, the increased risk of injury may be caused by the direct biological effect of alcohol, that is, a reduction in the person's ability to perceive and respond to hazards, such as has been well demonstrated for motor vehicle–related injury.[3] The direct biological effect can be further divided into two components: the direct effect of increased injury risk with increasing blood alcohol concentration, and the hangover or other chronic effects of alcohol, which may increase injury risk even when the blood alcohol concentration is zero. While our study could not separate out these effects, it does provide valuable information about the degree to which usual patterns of alcohol consumption affect injury risk. Most other studies have measured only direct alcohol involvement at the time of injury, and they have assumed if the blood alcohol concentration is not elevated that alcohol is not a factor. A recent study of problem drinking among trauma center patients, however, found the prevalence of problem drinking to be high even in persons who were sober at the time they were injured.[31] It is likely that the different effects of alcohol can interact with each other and affect injury risk in a variety of ways, as suggested by our finding that all three measures of drinking behavior were associated with the likelihood of injury's being the underlying cause of death. □

Maternal Smoking during Pregnancy and Smoking by Adolescent Daughters

Denise B. Kandel, PhD, Ping Wu, PhD, and Mark Davies, MPH

ABSTRACT

Objectives. Since cigarette smoking in adolescence represents a crucial entry point in the progression to illicit drugs, risk factors for adolescent smoking have public health implications. The influence of mothers on children's smoking appears to be greater than that of fathers. To explain the selective influence of mothers, we examined the consequences of maternal smoking during pregnancy in two longitudinal samples.

Methods. Analyses were conducted on follow-up interview data from two dyadic samples of mothers and firstborn adolescents for whom data on maternal smoking during and after pregnancy were available (192 mother–child pairs originating from New York State and 797 dyads from a national sample).

Results. In both samples, maternal smoking during pregnancy, when postnatal smoking was controlled, selectively increased the probability that female children would smoke and would persist in smoking (adjusted odds ratios of about 4).

Conclusions. The findings suggest that nicotine or other substances released by maternal smoking can affect the fetus, perhaps through the nicotinic input to the dopaminergic motivational system, so as to predispose the brain in a critical period of its development to the subsequent addictive influence of nicotine consumed more than a decade later in life. (*Am J Public Health.* 1994;84:1407–1413)

Introduction

Adolescents who experiment with drugs, and those who ultimately become heavy users, almost invariably first use cigarettes or alcohol.[1–3] Furthermore, the earlier an adolescent begins to experiment with cigarettes and alcohol, the greater the severity and persistence of his or her subsequent involvement with illicit drugs.[3] Thus, it is important to understand the factors that predict early initiation of drinking and cigarette smoking. Among these factors, smoking by parents seems particularly important.

To examine intergenerational effects on drug behavior, we followed a cohort of New York State adolescents for 19 years. In a separate analysis based on mother-father-child triads, we found that maternal smoking was related in a dose-dependent manner to smoking among both boys and girls.[4] The association with paternal smoking was weaker for both sexes. Differences between mothers and fathers were not explained by social influences. Here we report further analyses to identify the sources of the maternal effect in two longitudinal samples, one originally from New York State, the second a national sample. We focus on one factor that differentiates mothers from fathers, namely the mother's smoking behavior during her pregnancy.

Methods

The New York State Follow-Up Cohort

The New York State (NYS) Follow-Up cohort is from a representative sample of adolescents who were enrolled in grades 10 and 11 in NYS public high schools in 1971/72 and were followed for 19 years. The target population for the adult follow-up (n = 1651) was drawn from the enrollment list and included students absent from school at the initial 1971 survey to ensure the representativeness of the sample. Respondents were reinterviewed in 1980, 1984, and 1990, at the average ages of 24–25, 28–29, and 34–35 years; in 1990, 540 men and 620 women (72% of the original target group, excluding those deceased) were reinterviewed. Personal interviews were also conducted with the subjects' two oldest children aged 9–17 years and, when there was a child aged 6–17 years, with the subjects' spouses or partners. The completion rate for the first-born child was 90.5%. Informed consent was obtained from mothers for their own and their children's participation, and separately from the children. The subjects were 192 mothers (mean age = 34.5 years, SD = 0.8) and their first-born children aged 9–17 years (mean age = 12.9, SD = 2.4).

The structured personal interviews took on average 1½ hours to complete for adults and 1 hour for children. Information about the use of 12 classes of drugs within the last 12 months and detailed retrospective monthly drug use histories since the prior survey were obtained at each follow-up. Mothers' use of cigarettes and other drugs during pregnancy with

[f]No smoking vs < 1 pack, P <.01; no smoking vs ≥1 pack, P < .01.

the selected child and amount smoked were ascertained.

The National Longitudinal Survey of the Work Experience of Youth Cohort

The analyses were replicated on a second group of subjects obtained from the National Longitudinal Survey of the Work Experience of Youth (NLSY). This multistage stratified national probability sample, representative of youths born from 1957 through 1963 in the coterminous United States, was drawn in 1979 and interviewed annually thereafter. The 1979 interview completion rate was 90%; retention rates have consistently been over 90%. In 1990, 4510 women (91% of the target group) were interviewed, including 3088 mothers; 5803 children (90% of the target group) born to these mothers were assessed. Interviews were completed with 957 mothers and their oldest children aged 10–18 years.

Analyses were based on 797 of these dyads with complete data on child smoking and maternal smoking during and after pregnancy (mothers' mean age = 30.7 years, SD = 1.9; children's mean age = 12.5 years, SD = 1.9). Prenatal exposure to maternal tobacco and alcohol use was first ascertained in 1983 for the youngest child and in 1986 for all births not asked about previously (62.6% of the children). Questions about current maternal drug use, including cigarette smoking, were asked only in 1984. In 1990, children aged 10 years and older completed a self-administered questionnaire inquiring about cigarette smoking. Informed consent was obtained from mothers for their own and their children's participation.[5]

The NLSY data differ from the NYS data in several respects: (1) mothers were specifically asked whether they had smoked during the 12 months preceding the birth of their children and how much they smoked during the pregnancy; (2) the most recent measure of maternal smoking was obtained in 1984, 6 years prior to the children's assessment; (3) monthly drug histories were unavailable; and (4) children's current smoking was ascertained for the past 3 months, not for the last year.

Statistical Analysis

Pearson's chi-square test was used to test for homogeneity of rates in contingency tables. When this joint test was significant, pairwise rates in the 2 × 2 subtables were compared by using Pearson's chi-square test. Maximum likelihood estimation and hypothesis testing methods were used in the multivariable logistic regressions of binary indicators of the child's smoking behaviors on maternal age, education, and smoking behaviors.[6] The large sample estimates of the standard errors were used to construct confidence intervals. Odds ratios were pooled across samples and tested for significance with the Mantel-Haenszel method.[7,8] The statistical program SPSS (SPSS Inc, Chicago, Ill) was used for weighted calculations.

Results

NYS Analyses

Of the mothers, 40.7% smoked during pregnancy; 28.7% smoked throughout the pregnancy. Twenty-five percent of the male offspring and 25.8% of the female offspring ever smoked; 16.7% and 15.0%, respectively, smoked within the last 12 months. There is a significant association between maternal smoking during pregnancy and the child's smoking 13 years later (Table 1). This association is stron-

ger for the child's smoking during the last year than for ever smoking, and it is stronger for daughters than for sons. We controlled for maternal use of alcohol and marijuana during pregnancy and found that the smoking effect was not altered (data not shown). Only one woman reported using illicit drugs other than marijuana during her pregnancy.

The proportion of current smokers among ever smokers can be interpreted as a measure of persistence of smoking. Persistence of smoking among offspring is more highly related to maternal smoking during pregnancy for daughters than for sons (Table 2, A.).

Of mothers who smoked during their pregnancies, 77.7% were still smoking 13 years later. Since the effect of smoking during pregnancy could be confounded with the effect of current smoking, we carried out two analyses to examine the joint impact of maternal smoking behavior during and after pregnancy.

TABLE 2—Persistence of Child Smoking in Two Cohorts, by Maternal Smoking during Pregnancy and Sex of Child

Girls	26.9	(48)	72.2	(30)	15.2	<.001

Note. NYS = New York State; NLSY = National Longitudinal Survey of the Work Experience of Youth; NS = not significant.

[a]Percentage who continued to smoke (i.e., during the last 12 months in the New York State cohort and during the last 3 months in the National Longitudinal Survey of the Work Experience of Youth) among those who ever smoked.

In the first step, five groups of mothers were identified, depending upon whether they smoked during the pregnancy and within the year preceding the interview (Table 3, A.). The child's exposure to postnatal maternal smoking varied greatly across the groups. On average, mothers in group 2 had last smoked 14.3 years ago, mothers in group 4 had last smoked 6.5 years ago, and mothers in groups 3 and 5 were currently smoking. Total exposure, calculated by dividing the total number of months the mother smoked after childbirth by the child's age in months, ranged from 4% when mothers smoked neither during pregnancy nor within the last year (group 2) to 38% when mothers smoked during pregnancy but not within the last year (group 4), to 63% when mothers did not smoke during pregnancy but smoked within the last year (group 3), and to 91% when mothers smoked in both periods (group 5). The effect of maternal smoking during pregnancy on daughters is apparent across the groups. Rates of smoking among daughters were higher when mothers smoked during pregnancy but not within the last year (group 4) than when mothers did not smoke during pregnancy but did smoke within the last year (group 3). Yet the children of group 3 mothers were exposed to maternal smoking for twice as long in their lives, and much more recently, than the children of the group 4 mothers. Correlatively, the same proportions of daughters were currently smoking if their mothers smoked during pregnancy, irrespective of whether the mothers smoked within the last year. However, daughters of the currently smoking mothers (group 5) were exposed to postnatal maternal smoking for three times as long as daughters of the mothers who had not smoked within the last year (group 4); the latter mothers had last smoked more than 6 years ago. By contrast, recent smoking by sons appears to be more influenced by maternal smoking within the last year. The relationship of daughters' smoking rates to maternal smoking during pregnancy and the lack of relationships to child lifetime exposure and current maternal smoking further support the existence of a prenatal effect of maternal smoking.

In the second step, we estimated logistic regressions predicting the child's smoking—ever and within the year preceding the interview—in which we distinguished the amounts mothers smoked, both during pregnancy and currently (Table 4). (The second model shown did not differentiate maternal smoking during pregnancy according to quantities smoked.) The strongest positive effect of maternal smoking appears when the mother smoked during her pregnancy. This effect is evident only among daughters and is quite marked, regardless of the amount the mother smoked. By contrast, the mother's current smoking is nonsignificant but has a greater effect on boys than on girls.

A Replication in the NLSY Sample

To test the NYS results by replication, we carried out a parallel analysis in the NLSY sample. Of the mothers, 37.1% smoked during pregnancy; 21.5% of the boys and 19.6% of the girls ever smoked and 4.9% and 8.6%, respectively, smoked within the last 3 months. The child's smoking, especially current and persistent smoking (the proportion who smoked in the last 3 months among those who ever smoked), is related to maternal smoking during pregnancy (Tables 1 and 2, B.). As in the NYS sample, the effect was stronger on daughters than on sons.

Also as in the NYS sample, smoking during pregnancy was highly related to smoking afterward: 89% of mothers who had smoked during pregnancy were smoking at the time of the 1984 interview (an average of 6 to 7 years after pregnancy). The joint classification of maternal smoking during and after pregnancy reveals the stronger impact of smoking during pregnancy than afterward and on daughters than on sons (Table 3, B.).

To identify the unique effect of prenatal maternal smoking, we estimated the same logistic regressions for the NLSY sample as for the NYS sample (Table 5). Again, maternal smoking during pregnancy was associated with current and persistent smoking by daughters but not sons. Contrary to the results of the NYS analysis, there was no increased risk of the child's ever smoking due to maternal smoking during pregnancy, and the significant effect on daughters' current smoking was found among mothers who reported smoking less than a pack of cigarettes a day during pregnancy, rather than a pack or more. Heavy maternal smoking 6 years prior to the child's

*$P < .001$; **$P \leq .01$; ***$P < .05$.

Tables 4 and 5). A Mantel-Haenszel chi-square test of the common underlying association between mother's and daughter's smoking across the two samples is statistically significant ($P < .01$).

To test the hypothesis that the effect of maternal prenatal smoking is stronger for daughters' persistence of smoking than for experimentation with cigarettes, we conducted a logistic regression predicting persistent smoking among adolescents who had ever smoked in the NLSY cohort. Maternal smoking during pregnancy increased the odds of persistent smoking by daughters more than four times, but had no effect among sons (Table 5). The adjusted odds ratios for daughters were statistically significantly different from those for sons. The small sample size precluded the implementation of a sex-specific analysis of persistence in the NYS sample.

Discussion

Although the sample sizes were small, the strength of our findings derives from the test of an a priori hypothesis in one sample and a replication in a second sample. In both, the maternal effect of smoking during pregnancy was stronger on daughters than on sons, and in one sample it was clearly stronger for the child's current smoking and for persistence than for lifetime experimentation.

The impact of maternal smoking during pregnancy on the child's smoking, and especially the differential impact on current smoking compared with ever smoking, is consonant with the existence of a prenatal effect. Such a biological effect should be stronger for persistent and heavy smoking than for simple experimentation; the latter should be more responsive to social influences. The inconsistent findings between the two samples regarding the dose effects parallel findings regarding the effect of prenatal smoking in lowering birthweight.[9] It would be especially important to replicate the analyses in a prospective cohort in which detailed maternal drug use could be assessed during pregnancy.

One mechanism underlying the maternal effect and its greater impact on female than male children might be an intrauterine effect of nicotine on the developing brain of the fetus. Some motivational consequences of reinforcing stimuli, including the craving from drug dependence, are mediated by the mesolimbic and mesocortical components of the dopaminergic system.[10-14] Drug withdrawal leads to decreased activity in components of the dopaminergic system that are clinically manifested in craving. Drug intake restores the rewarding effects

of dopaminergic transmission.[15,16] Nicotine, which crosses the placental barrier and stimulates the action of cholinergic neurons, enhances activity in the dopaminergic system.[13]

Our data raise the possibility that during a critical prenatal period of brain development, nicotine, or other substances released by maternal smoking, may modify the properties of the dopaminergic system of the brain so as to change the threshold of this system (or related systems) to the effects of nicotine at a later time in life and thereby predispose the child to smoke and to persist in smoking. This suggestion is consistent with the notion that nicotine, like other addictive drugs, can alter gene expression and can produce long-lasting functional and structural changes in dopaminergic neurons,[10] an effect that might be particularly profound in the developing brain. The finding that nicotine administered to pregnant mice increases adenylate cyclase activity in the midbrain and brainstem at postpartum and that the levels return to normal within 4 weeks, only to recur in adulthood,[17] lends support to this interpretation.

Why the intergenerational transmission of smoking from mother to child should be stronger for female children than for males is unclear. Perhaps these sex differences reflect the distinctive sexual dimorphism of the brain—including hormonal and structural factors—that emerges during fetal development.[18,19] For example, the release of androgens may protect the male infant against the priming effect of nicotine.

Maternal prenatal exposure to drugs may have two types of consequences for the child: immediately manifest consequences, most clearly evident in crack babies or infants with the fetal alcohol syndrome, and latent consequences that may require more than a decade to become manifest, as may be the case for smoking. The prenatally induced predisposition to smoke might be enhanced further by passive smoking after birth, which would facilitate the child's desire to experiment with cigarettes and his or her potential dependence on tobacco. We could not measure exposure to passive smoking by other household members. We assumed that the effects of passive smoking would be captured by postnatal maternal smoking. Since we showed that postnatal maternal smoking did not retain a unique statistically significant effect and since we had previously shown that current maternal smoking was more important than paternal smoking,[4] we conclude that the prenatal maternal effect is stronger than the effect of subsequent passive smoke. Subtle physiological effects deriving from the child's exposure to prenatal maternal smoking may create in these children a low level of nicotine dependence without their ever having smoked a cigarette. These differences could be reflected in the child's initial response to nicotine and result in tolerance and persistence of smoking. Our data do not exclude a variety of additional social or physiological effects, including a genetic predisposition to smoking, reflected in differential regulation of brain nicotinic receptor numbers and response to nicotine.[15,16] Such a genetic predisposition might be especially strong among women who continue to smoke during their pregnancies despite the well-advertised hazards of doing so.

The present findings are consonant with an increasing body of research that documents latent and deferred effects of fetal exposure to a variety of insults not limited to drug use. Thus, the classic studies on the Dutch famine during World War II have identified adult effects of prenatal food deprivation on obesity and schizophrenia.[20,21] Interestingly, the schizophrenia effects are somewhat stronger among women than among men.

Independent of its mechanism, our evidence indicates that maternal smoking during pregnancy may create a serious risk for smoking dependence in female offspring, a risk that is even greater than that created by the mother's current smoking. Young women have not shown the decline in smoking observed among other adults in the United States.[22] From a public health perspective, it is essential to target these young women for prevention and intervention, since a reduction in their rates of smoking may have unanticipated benefits for the second generation in addition to the direct health benefits for the adult smokers themselves. □

Call for Papers on Worksite Health Programs

Health Education Quarterly, the official journal of the Society for Public Health Education, announces a call for original manuscripts for a theme issue on worksite health programs. The worksite is a common context within which health promotion, disease prevention, and injury prevention programs are conducted. This theme issue is intended to serve as a forum for those interested in occupational and worksite health and to foster a dialogue between those involved in worksite health promotion and those in occupational health and safety.

The journal invites practitioners, researchers, policymakers, and interested others to submit manuscripts that accomplish any of the following:

- Describe the development, implementation, and evaluation of a worksite health promotion, disease prevention, or injury prevention intervention (e.g., descriptions of methods for gaining employee and organizational commitment to and active participation in worksite health programs; innovative needs assessments; methods for maintaining interest in and commitment to a program over time; process and/or outcome evaluations of worksite interventions)
- Investigate factors that affect worksite health programs and the practice of health educators within those programs (e.g., research studies addressing organizational, work group, or employee characteristics related to successful worksite health programs)
- Address important issues in worksite health programs and integrate the worksite health promotion and occupational health and safety perspectives (e.g., literature reviews or conceptual "think pieces" that address such crosscutting issues as rectifying health status goals with organizational profit maximization goals; addressing the possibility that either explicit or subtle coercive influences affect employees' decisions to participate in worksite health programs or to practice safe work behaviors; accommodating multiple stakeholders' divergent points of view that contribute to program planning or policy decisions)
- Describe methods or tools available to individuals who conduct or evaluate worksite health interventions (e.g., use of biomarkers, industrial hygiene methods)

All papers will be subject to peer-review procedures. Authors should consult the "Information for Authors" in *Health Education Quarterly* for style requirements. Manuscripts will be accepted until *February 28, 1995,* and should be submitted to Catherine A. Heaney, PhD, MPH, The Ohio State University, Department of Preventive Medicine, B-215 Starling Loving Hall, 320 W 10th Ave, Columbus, OH 43210; tel (614) 293-3908.

An Evaluation of the Kessner Adequacy of Prenatal Care Index and a Proposed Adequacy of Prenatal Care Utilization Index

Milton Kotelchuck, PhD, MPH

ABSTRACT

Objectives. The assessment of the adequacy of prenatal care utilization is heavily shaped by the way in which utilization is measured. Although it is widely used, the current major index of utilization, the Kessner/Institute of Medicine Index, has not been subjected to systematic examination. This paper provides such an examination.

Methods. Data from the 1980 National Natality Survey are used to disaggregate the components of the Kessner Index for detailed analysis. An alternative two-part index, the Adequacy of Prenatal Care Utilization Index, is proposed that combines independent assessments of the timing of prenatal care initiation and the frequency of visits received after initiation.

Results. The Kessner Index is seriously flawed. It is heavily weighted toward timing of prenatal care initiation, does not distinguish timing of initiation from poor subsequent utilization, inaccurately measures utilization for full- or post-term pregnancies, and lacks sufficient documentation for consistent computer programming.

Conclusions. The Adequacy of Prenatal Care Utilization Index offers a more accurate and comprehensive set of measures of prenatal care utilization than the Kessner Index. (*Am J Public Health.* 1994;84:1414–1420)

Introduction

Accurate assessment of prenatal care utilization is the critical first step in the development of public health programs to improve prenatal care accessibility and ultimately to improve birth outcomes. The assessment of the adequacy of prenatal care utilization is heavily shaped by the way in which utilization is measured.

Currently, there are two widely used measures of adequacy of prenatal care utilization: the trimester of prenatal care initiation and the Kessner/Institute of Medicine (IOM) Adequacy of Prenatal Care Index.[1] Trimester of initiation will not be examined here because it provides no information about prenatal care utilization after initiation; it has been critically examined elsewhere.[2,3] The Kessner Index—the principal adequacy of prenatal care utilization index in use in the United States today—includes information about both the timing of prenatal care initiation and prenatal care visits after initiation. It was published in 1973 as part of an IOM-supported study of infant mortality in New York City.[1] The Kessner Index combines two continuous numeric measures (month prenatal care begins and number of visits, adjusting for length of gestation) and rigidly links them into a very easy to understand index with three levels of adequacy (Adequate, Intermediate, and Inadequate). To be rated Adequate on the Kessner Index, one must start prenatal care in the first trimester and have nine prenatal care visits for a normal-length pregnancy.

Table 1 presents the Kessner Index algorithm as initially published. In this original description, public or private obstetric service was a third factor, but this factor has been dropped by all subsequent researchers because the type of service is not noted on the standard US birth certificate and because researchers disagree with the index's assumption that care from public services can never be adequate.[4–7] Although Kessner et al. called their index the "Adequacy of Prenatal Care Index," their measure indicates nothing about the content or clinical adequacy of prenatal care: it is a utilization index only.

The Kessner Index has been widely adopted for public health research, planning, and resource allocation. However, it appears that the index was not subjected to close scrutiny prior to its widespread adoption. The accuracy of the Kessner Index is critical because any limitations may distort our perceptions about prenatal care adequacy in the United States and may incorrectly influence programmatic efforts to improve prenatal care utilization. The Kessner Index has also been widely used to assess the association between prenatal care and birth outcomes.[4–7] The limited positive associations noted may be more a reflection of the internal characteristics of the Kessner Index than of the true strength of that relationship.

The ability to measure prenatal care utilization after initiation remains underdeveloped. The Kessner Index does not separately isolate utilization after enrollment, nor does any other prenatal care index. Yet a distinction between initiation

and utilization once in care may have differential implications for birth outcomes and for prenatal care program practices.

In this paper I examine the characteristics and limitations of the Kessner Adequacy of Prenatal Care Index and propose an alternative, the two-factor Adequacy of Prenatal Care Utilization Index.

Database

The database for this paper is the National Center for Health Statistics' 1980 National Natality Survey, a representative sample of US births in 1980.[8] This survey uses a follow-back methodology involving the collection of data from four sources: maternal retrospective information, physician and hospital records, radiologic records, and birth and death certificates. Data are available on 9941 live births, oversampled (4:1) for low-birthweight infants. Responses were weighted by a poststratification ratio estimate procedure to be representative of the 1980 US birth cohort. Prenatal care information is absent for 15% of the births. All missing data were imputed via a categorical matrix hot-deck methodology. Details of the survey and study population are described elsewhere.[9]

All data used in this paper are derived from the birth certificate data source only. The birth certificate data were chosen because they are readily available to the public health community, they are the principal database for the assessment of a community's prenatal care utilization adequacy, and they are available for all married and unmarried women in the 1980 National Natality Survey.

Kessner Index Assessment

The Kessner Index is a seriously flawed index of adequacy of prenatal care utilization. Four features merit attention.

First, the Kessner Index is principally a measure of the timing of initiation of prenatal care. The Kessner Index algorithm requires that to be rated Adequate, prenatal care must begin in the first trimester; to be rated Intermediate, care must begin in the second trimester; and to be rated Inadequate, care must begin in the third trimester or not at all. The additional factor in the Kessner Index, the number of prenatal care visits, can only lower the rating category. This rarely happens. Table 2 shows that the trimester of care overwhelmingly (for 86.2% of women) predicts the Kessner Index rating. Only 13.8% of women have their ratings reduced owing to insufficient visits.

Second, the Kessner Index does not distinguish inadequacy of care due to late initiation from inadequacy of care due to insufficient number of visits. Table 3 shows that these two implicit subscales have distinctive distributions. Overall, 24.7% of US women would be classified differently if the two were measured separately. More striking, 61.1% of women starting prenatal care in the second trimester (rated Intermediate by the Kessner Index) and 45.6% of women starting prenatal care in the last trimester or not at all (rated Inadequate by the Kessner Index) would be classified differently based on an index with two distinctive factors.

Third, the Kessner Index is unable to adequately characterize prenatal care utilization for normal-gestation and postmature births. For all normal-length pregnancies (more than 36 weeks' gestation), the Kessner Index requires only nine visits for care to be Adequate. Yet up to 36 weeks' gestation, the Kessner Index adjusts the

TABLE 1—Three-Factor Health Services Index Controlled for Gestation and Based on Number of Prenatal Visits, Interval to First Prenatal Visit, and Type of Hospital Service

Medical Care Index	Gestation (Weeks)		Number of Prenatal Visits
Adequate[a]	13 or less	and	1 or more or not stated
	14–17	and	2 or more
	18–21	and	3 or more
	22–25	and	4 or more

required number of visits according to the well-established American College of Obstetricians and Gynecologists (ACOG) recommendations (one visit per month through 28 weeks' gestation, one visit every 2 weeks through 36 weeks' gestation, and one visit per week thereafter).[10] No discussion of the rationale for stopping at nine visits is presented.

It would appear that the index stops at nine visits because only one digit was allocated to record the number of prenatal care visits on the 1968 New York City computerized birth certificate file used in the Kessner et al. analyses.[1] According to ACOG, nine visits corresponds to the recommended number of visits at 36 weeks' gestation; hence the index's adjustments for gestational age stop at that point. Thus, the Kessner Index is constructed on the basis of an outdated computer data storage limitation. Full-term births can, therefore, be rated as having Adequate prenatal care even if they have had fewer than the ACOG-recommended number of visits. The longer the pregnancy, the smaller the percentage of recommended visits needed for care to be rated Adequate. Only premature births (36 weeks' gestation and less) are assessed fully against the ACOG standards.

If one extrapolates the original Kessner Index algorithm beyond the nine visits, using the ACOG standards (e.g., 10 visits by 37 weeks, 11 visits by 38 weeks, etc.), a major redistribution of prenatal care utilization adequacy would occur (Table 4). There would be more than twice the number of women with Inadequate care, a major increase and shift to Intermediate care, and many fewer women with Adequate prenatal care. Indeed, 44% of all women would now be classified as having less adequate prenatal care than previously classified. If one examines the extrapolation stratified by weeks' gestation at delivery, as in Table 5, one sees that this miscategorization increases as gestational age advances.

Finally, the lack of adequate initial documentation for the Kessner Index has led to nonstandardized definitions and discrepancies in its calculations. The algorithm presented in Table 1 appears to be the sole documentation for the Kessner Index. This is clearly inadequate. In particular, there is insufficient description of how to treat records with missing gestational age, missing visits, missing initiation date, etc.[11] The result is that each public health entity has had to program the index itself, with resultant inconsistencies. For example, many states

have added an "unknown" category if number of prenatal care visits or timing of first visit is unknown, while others still follow the original recommendations and record such births as having received "inadequate" care. Some states impute missing gestational age on the basis of birthweight, whereas others (e.g., New York) disregard all such records or disregard only those that cannot be rated as "inadequate" (L. Dellehunt, written communication, September 29, 1986). The state of Missouri and others have further simplified the definition of the Adequate rating of the Kessner Index to eight visits for full-term birth and five visits for premature births (J. W. Stockbauer, written communication, September 26, 1986). Thus, the Kessner Index ratings may not be comparable across sites.

Adequacy of Prenatal Care Utilization Index

The weaknesses of the Kessner Index led the author to try to develop an alternative prenatal care utilization algorithm, based on birth certificate data. The proposed Adequacy of Prenatal Care Utilization (APNCU) Index attempts to characterize prenatal care utilization on two independent and distinctive dimensions: Adequacy of Initiation of Prenatal Care and Adequacy of Received Services (once prenatal care has begun). This two-factor index does not assess the quality of the prenatal care that is delivered, but simply its utilization.

The initial dimension, Adequacy of Initiation of Prenatal Care, characterizes the adequacy of the timing of initiation of care. The month prenatal care begins, which is recorded on the birth certificate, corresponds directly to the adequacy of timing of initiation of prenatal care. The underlying assumption is that the earlier the initiation, the more adequate the prenatal care. The month in which care is initiated is grouped not by trimester, but into four slightly different adequacy groupings: months 1 and 2, months 3 and 4, months 5 and 6, and months 7 through 9. The second trimester was felt to cover too broad a time period to be useful as a single initiation date category. No prenatal care, which can be isolated in this index, is grouped in the late or inadequate care category for this dimension.

The second dimension, Adequacy of Received Services, characterizes the adequacy of the prenatal care visits received during the time the woman is actually in prenatal care (i.e., from initiation until the delivery). The expected number of visits is based on the ACOG prenatal care visitation standards for uncomplicated pregnancies,[12] adjusted for the gestational age at initiation of care and for the gestational age at delivery. The measure for Adequacy of Received Services is the ratio of the actual number of visits to the expected number of visits.

The expected number of visits for each pregnancy can be calculated easily (by computer or by hand) by noting the number of ACOG-recommended prenatal care visits for a pregnancy of a given gestation and then adjusting or reducing that number based on the gestational age at initiation of care (missed visits are assumed not to be made up). Essentially, this procedure measures a segment of a fixed recommended prenatal care utilization metric, but in contrast to the Kessner Index, it is adjusted at two places: when the woman begins prenatal care and when she delivers. For example, for a 40-week pregnancy, ACOG recommends 14 visits; if care began in month 4 (three missed visits), then the expected number of visits would be 11. The number of actual or observed visits can be directly recorded from the birth certificate (or any other prenatal care data source). The ratio of observed to expected visits is then grouped into four categories: Inadequate (less than 50% of expected visits), Intermediate (50%–79%), Adequate (80%–109%), and Adequate Plus (≥110%). A similar ratio concept is implicit in the existing Kessner Index, wherein inadequate visits equal approximately 50% of adequate visits. These four percentage categories allow for a slightly broader range of numbers of visits to be rated as Adequate care (80%–109%) and provide, for the first time, a measurement of prenatal care utilization that exceeds ACOG standards. This dimension of Adequacy of Received Services is independent of the previously described dimension of Adequacy of Initiation of Prenatal Care.

The two dimensions can be combined into a single summary prenatal care utilization index. Inadequate utilization is defined as either late initiation (after the 4th month of pregnancy) or less than 50% of recommended visits. All other categories require initiation of care by the 4th month of pregnancy and then are coded according to the extent of received services (e.g., to be rated Adequate Plus requires initiation of care between 1 and 4 months and more than 110% of the expected ACOG-recommended visits, etc.). Figure 1 portrays the construction of the summary APNCU Index.

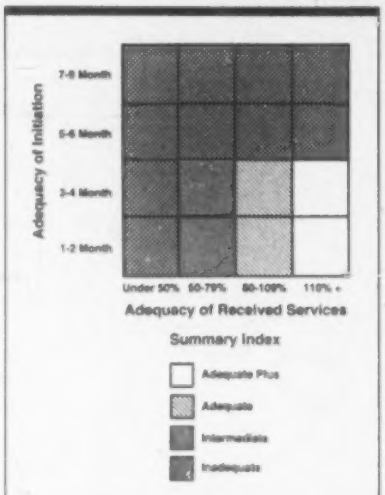

FIGURE 1—The summary Adequacy of Prenatal Care Utilization Index.

A descriptive outline of the proposed index and its two factors is presented in Table 6. (A more detailed description of the APNCU Index and its coding assumptions and an SAS Program for its computation are available from the author.)

Table 7 presents a comparison of the APNCU and Kessner Index ratings. Only 71.5% of women in the United States would be rated the same on the two indexes (assuming the APNCU's "Adequate and Adequate Plus" equal Kessner's "Adequate"), with 21.1% achieving a poorer rating and 7.4% an improved rating. Women whose care was rated Intermediate on the Kessner Index would be the most likely to be recategorized: 34% would now be rated Inadequate and 28% rated Adequate or Adequate Plus.

In a related paper in this issue of the Journal I apply the APNCU Index to the 1980 National Natality Survey data to assess the adequacy of prenatal care utilization in the United States and its association with low birthweight.[13]

Discussion

The assessment of the adequacy of prenatal care utilization is heavily shaped by the way in which utilization is measured. One of the major strategic and programmatic thrusts to reduce infant mortality in this era is to increase early initiation of prenatal care. *Healthy People*

TABLE 6—Outline of the Adequacy of Prenatal Care Utilization Index

I. Month prenatal care began (Adequacy of Initiation of Prenatal Care)
   - Adequate Plus: 1st or 2nd month
   - Adequate: 3rd or 4th month
   - Intermediate: 5th or 6th month
   - Inadequate: 7th month or later, or no prenatal care

II. Proportion of the number of visits recommended by the American College of Obstetricians and Gynecologists received from the time prenatal care began until delivery (Adequacy of Received Services)
   - Adequate Plus: ≥ 110%
   - Adequate: 80–109%
   - Intermediate: 50–79%
   - Inadequate: < 50%

III. Summary Adequacy of Prenatal Care Utilization Index
   - Adequate Plus: Prenatal care begun by the 4th month and 110% or more of recommended visits received
   - Adequate: Prenatal care begun by the 4th month and 80%–109% of recommended visits received
   - Intermediate: Prenatal care begun by the 4th month and 50%–79% of recommended visits received
   - Inadequate: Prenatal care begun after the 4th month or less than 50% of recommended visits received

TABLE 7—Ratings Assigned to Births According to the Adequacy of Prenatal Care Utilization Index Compared with the Kessner Index

Kessner Index	Adequacy of Prenatal Care Utilization Index: Inadequate, %	Intermediate, %	Adequate, %	Adequate Plus, %	% of Total Births
Inadequate	7.7	0.0	0.0	0.0	7.7
Intermediate	8.9	10.1	5.0	2.4	26.3
Adequate	.1	12.1	38.3	15.4	65.9
% of total births	16.7	22.2	43.4	17.7	100.0

Note. Percentages are those of all US births; they may not add to 100 because of rounding.
Source. Percentages are based on an analysis of birth certificate data from the 1980 National Natality Survey.[8]

2000's goal 14.11 is to increase first-trimester prenatal care to at least 90% of live births.[14] By contrast, continuity of prenatal care once enrolled is much less emphasized. Professional and public attention has been drawn to the theme of early access to care, I believe, because we have been able to marshal clear evidence about prenatal care initiation but we lack any readily available measures of care after enrollment. Both current popular measures of prenatal care adequacy, trimester of initiation of care (by definition) and the Kessner Index (by algorithmic biases), are basically measures of initial access to care. Improving birth outcomes, however, may be dependent on other features of prenatal care (such as content, timing, and number of visits). One utilization measure may not capture all facets of prenatal care.

The Kessner Index was a major achievement in perinatal health service research, transforming two technically available but continuous and complex data items on birth certificates into a simple three-point utilization scale. Its original rationale and basic algorithm seemed clear and clinically reasonable. Unfortunately, the Kessner Index appears to be seriously flawed; it may be leading us to misperceive the nature of prenatal care utilization in the United States. Four limitations were noted in this paper.

First, the Kessner Index is overwhelmingly a measure of the initiation of prenatal care. Only 14% of women receive fewer visits than the number required for the trimester they enter care. This initiation bias may explain why those who have used both the Kessner Index and the trimester of prenatal care initiation note so little difference between them in most analyses; the latter measure is therefore preferred because it does not require the often inaccurately recorded or missing gestational age variable in its calculations (J.C. Kleinman, PhD, verbal communication, November 6, 1987). Second, the Kessner Index does not distinguish between inadequacy due to late initiation and inadequacy due to an inadequate number of visits. Although the summary Kessner Index was not developed to measure these components separately, the absence of independent measures results in the loss of important information about the nature of prenatal care adequacy, especially since 24% of women would be rated differently on these two dimensions. Neither of these first two observations about the Kessner Index, through interesting, would seem to warrant its dismissal.

The limitation of the Kessner Index to nine visits is, however, critical. This limitation is totally arbitrary and not clinically derived; it is the direct result of a computer data capacity limitation of the 1968 New York City birth file. For 20 years, the US public health profession has based its major index of prenatal care adequacy on an algorithm developed to accommodate this single-digit limitation in the counting of the number of prenatal care visits.

Because of the nine-visit limitation, the Kessner Index incorrectly assesses prenatal care utilization adequacy for normal and post-term births, the vast majority of births in the United States. The extrapolated Kessner Index algorithm would indicate that only 29%, not 66%, of births receive "adequate" care. This is not a minor difference in our perception of the extent of prenatal care adequacy in the United States. Accurate assessment of prenatal care utilization for term infants may be particularly important, given the significant racial disparities in birth outcomes for normal-birthweight infants[15] and the recent observations that there are significant Black–White differences in the utilization of prenatal care at the end of pregnancy.[16,17] Moreover, the limitation to nine visits also biases the assessment of the relationship of prenatal care and birth outcomes. Full-term babies, which are bigger and more frequently healthy, are more readily rated as having received "adequate" care than are preterm babies, thus artificially enhancing the association of positive birth outcomes with more positive prenatal care adequacy ratings.[18] This bias suggests that the

current literature using the Kessner Index may be overstating the limited but positive association previously noted.[3,19]

Finally, the lack of documentation for the Kessner Index, not surprising in a less computer-intensive era, has resulted in different computations of the Kessner Index in different localities. Alexander et al.[11] have shown in great detail how different coding conventions regarding missing data can result in major differences in the measurement of prenatal care adequacy and the evaluation of perinatal care programs such as Medicaid.

The proposed APNCU Index attempts to correct these four limitations of the Kessner Index. The independent assessment of prenatal care utilization after initiation, adjusted for the full range of gestational ages, is clearly the most important new feature of the APNCU Index. It provides information and a perspective on prenatal care utilization that is not presently available to the US public health community. This is important because many maternal and child health intervention programs are targeted toward continuity of prenatal care services or enhancement of services once a woman has entered care (e.g., case management, risk screening, home visitations). This new component should allow for a more direct assessment of these initiatives, independent of the timing of initiation of care. Recent Medicaid enhancements appear to have differential effects on the two different components of prenatal care utilization.[20,21]

The establishment of an Adequate Plus category, another innovative feature of the APNCU Index, provides a means to directly estimate the number of women receiving more than the ACOG-recommended number of visits, adjusted for the timing of care initiation. It appears that it is important to isolate this fairly large group of high-risk women because they have a disproportionate number of the low-birthweight babies.[13] Efforts to isolate this high-risk group based simply on an absolute number of visits (13+) will not be accurate, incorrectly classifying many women who start prenatal care late or who are post-term.

Though not emphasized in the data presentations in this paper, the APNCU Index does allow for the direct ascertainment of the extent of "no prenatal care" as a subcategory of Inadequate prenatal care. Several perinatal analysts have emphasized the importance of distinguishing between these two groups.[22,23]

The proposed APNCU Index can be seen as a second-generation prenatal care adequacy index. The APNCU Index was developed in 1987 and improved through feedback from multiple early users. The current version (III) includes an Adequate Plus category in the Summary Index; distinguishes "no prenatal care" within the Inadequate care category; has further clarified the coding of "no data," "missing data," and unusual data combinations; and allows users to adapt the computer program for unusual coding conventions in their own databases. The present version is basically a very minor revision of the prior APNCU Index's algorithms.

There are limitations to this new APNCU Index. First, it does not measure the adequacy of the content of prenatal care, but merely that of the utilization of prenatal care; hence its name. Second, the APNCU Index is only as accurate as the data (birth certificate or otherwise) used to calculate it. Inaccuracies in birth certificate data have been well documented, especially for prenatal care information[2] and gestational age.[24] Third, this index has the opposite bias of the Kessner Index: the longer the pregnancy, the more opportunity to miss prenatal care visits, and hence the less likelihood of a rating of Adequate or Adequate Plus.[18] This bias is not, however, built into the structure of the index; the adequacy ratings accurately reflect the increasing difficulty that women have in meeting the demanding ACOG recommendations as the pregnancy continues. Fourth, the present APNCU Index does not adjust for the risk conditions of the mother. The ACOG recommendations are for women with uncomplicated pregnancies; thus, the APNCU Index produces a slightly conservative estimate of inadequate prenatal care utilization because it underestimates the true need for prenatal care visits.

Conclusions

The proposed APNCU Index, with its two components, provides a more accurate and comprehensive set of measures of prenatal care utilization than the widely used Kessner Index. The accurate measurement of prenatal care utilization is a critical step in the development of public health programs to improve prenatal care services and ultimately to improve birth outcomes. □

Call for Papers for New Journal of Sudden Infant Death Syndrome and Infant Mortality

Although sudden infant death syndrome (SIDS) is the major cause of infant death after the first 2 weeks of age, there is no journal devoted to SIDS. The *Journal of Sudden Infant Death Syndrome and Infant Mortality* will fill this gap by providing an international forum for the presentation and discussion of information that contributes to the understanding of SIDS and of other unexpected deaths in the vulnerable postneonatal period. This quarterly, peer-reviewed publication will include original articles on basic research and clinical studies, scholarly reviews, symposia proceedings, and book reviews. To support the goal of understanding the pathophysiology of SIDS, the journal will be concerned with new information about normal infant development, as well as with broad aspects of unexpected infant deaths. In addition, the journal will present articles that explore bereavement and counseling issues.

The *Journal of Sudden Infant Death Syndrome and Infant Mortality* is intended for researchers, clinicians, other health care professionals, and families affected by SIDS who will benefit from up-to-date information on the progress of SIDS research and prevention. The journal's editor-in-chief is Lois M. Roeder, director of the Professional Training and Education Unit, Sudden Infant Death Syndrome Institute, Department of Pediatrics, University of Maryland School of Medicine. The journal will be published under the auspices of the Sudden Infant Death Syndrome Institute at the University of Maryland, Baltimore.

For submission information, contact Lois M. Roeder, ScD, Editor-in-Chief, SIDS Journal, SIDS Institute, 22 S Greene St, Room N5W67, Baltimore, MD 21201-1595.

For subscription information, contact Journals Customer Service, Plenum Publishing Corporation, 233 Spring St, New York, NY 10013; tel (800) 221-9369 or (212) 620-8470/71.

Prenatal Alcohol Exposure, Birthweight, and Measures of Child Size from Birth to Age 14 Years

Paul D. Sampson, PhD, Fred L. Bookstein, PhD, Helen M. Barr, MA, MS, and Ann P. Streissguth, PhD

ABSTRACT

Objectives. The purpose of the study was to examine the effect of prenatal alcohol exposure on offspring's weight, height, and head circumference from birth through 14 years of age.

Methods. This longitudinal prospective study examined a cohort of approximately 500 offspring (oversampled for heavier drinkers and stratified for smoking from a population of 1529 women in prenatal care at the 5th gestational month) at birth; 8 and 18 months; and 4, 7, and 14 years of age. Covariates were examined by means of multiple regression. Birth size measures were also examined as predictors of 7-year neurodevelopmental outcomes.

Results. Effects of alcohol were observed on weight, length, and head circumference at birth; these effects were not altered by adjustment for covariates including smoking. However, the birthweight effect is clearly transient: although alcohol effects remained observable at 8 months, they were not measurable thereafter through age 14 years.

Conclusions. In this population-based sample, neither birthweight nor any later size measure was as useful an indicator of the enduring effects of prenatal alcohol exposure as were certain neurodevelopmental outcomes. (*Am J Public Health.* 1994; 84:1421–1428)

Introduction

There is a substantial literature on the association between maternal alcohol consumption during pregnancy and decreased neonatal weight, length, and head circumference. Indeed, one of the three defining characteristics of fetal alcohol syndrome is prenatal onset growth deficiency. However, conflicting results have been reported across studies of alcohol consumption at less than extreme levels (levels not as high as frank maternal alcoholism). Among the prospective studies that have measured neonatal size directly, several have found effects of alcohol exposure on birthweight (effects varying in magnitude and, in at least one case, depending on whether or not the mother smoked).[1–14] Other studies have not.[15–20] As Zuckerman and Hingson noted, these studies vary widely in sample ranges and variances of dose, in the timing and patterns of exposure, in the nature of the dose measurement(s) chosen, in the protocol for that assessment, and in the distributions of, and correction for, other factors affecting neonatal size.[21]

Regarding long-term consequences of fetal alcohol exposure for child size, Day et al. found increasing effects through age 36 months[22–24]; Russell et al. found height and head circumference effects at 6 years[25]; and Coles et al. found effects only on head circumference at 5½ years.[26] On the other hand, O'Connor et al. found no size effects at 12 months[27]; Fried and O'Connell found no effects at 12 or 24 months[10]; and Greene et al. found no conclusive evidence for persistence of effects through the preschool years (through age 4 years, 10 months).[13]

In this paper we attempt to clarify this literature from the perspective of our analyses of data from the Seattle Longitudinal Prospective Study on Alcohol and Pregnancy. These analyses permit us to follow the effects of prenatal exposure (at moderate levels) on children's growth in a sample that is reasonably balanced with respect to the principal competing teratogenic hypothesis—smoking-related deficiency of birthweight—and that offers multiple measures of dose. There is no doubt that alcohol doses in this range have substantial, enduring effects on the neurobehavioral development of the child through 14 years of age.[27–34] In this paper we ask whether these neurobehavioral effects are related to the effects of alcohol on size. Behavioral teratology tenets would suggest they need not be.[35]

We find that there is a distinct effect of prenatal alcohol exposure on measures of size at birth that can be detected with variable sensitivity by a variety of dose measures. The effect is shared across height, weight, and head circumference. After the age of 8 months the effects on size are essentially lost. Furthermore, the amount of apparent neonatal growth deficiency does not correlate with or

TABLE 1—Descriptive Statistics for Prenatal Alcohol Scores for the 436 of 553 Mothers Who Did Not Abstain Just Prior to and during Pregnancy

	Mean	SD	Minimum	Median	Maximum
Average ounces of absolute alcohol per day					
Prior to pregnancy recognition	0.74	1.61	0	0.35	25.76[a]
During pregnancy	0.33	0.63	0	0.15	8.55
Quantity-frequency-variability index					
Prior to pregnancy recognition	3.35	1.23	1	3	5
During pregnancy	2.99	0.99	1	3	5
Binge drinking (5 drinks or more on any occasion)					
Prior to pregnancy recognition	0.36	0.48	0	0	1
During pregnancy	0.24	0.43	0	0	1
Maximum no. of drinks reported on any occasion					
Prior to pregnancy recognition	3.77	2.79	0	3.50	13.00
During pregnancy	3.49	2.61	0	3.50	13.00
Monthly occasions of drinking					
Prior to pregnancy recognition	15.62	21.67	0	1.70	5.48
During pregnancy	8.40	12.85	0	0.92	4.80
Average no. of drinks per occasion					
Prior to pregnancy recognition	2.32	1.57	0	0.92	2.64
During pregnancy	2.12	1.18	0	0.92	2.64

Note. All skewed distributions were log-transformed for analysis.
[a]This score was an extreme outlier; the next highest score was 9.14 ounces.

predict later neurobehavioral consequences of the prenatal exposure.

Methods

The Seattle Longitudinal Prospective Study on Alcohol and Pregnancy began in 1974 when a consecutive sample of pregnant women planning to deliver at either of two hospitals (n = 1529) were interviewed during their 5th month of pregnancy regarding their smoking, drinking, and drug use during pregnancy. A follow-up cohort of approximately 500 children was selected at birth, oversampled for heavier alcohol exposure and stratified for smoking and alcohol in order to include children born to mothers ranging from heavy drinkers to infrequent drinkers and abstainers and to include both smokers and nonsmokers at all levels. (For further details see Streissguth et al.[29,33,36]) Both the prenatal sample and the follow-up cohort were primarily White, married, and middle class. Approximately 80% of the women reported drinking during pregnancy, but fewer than 1% reported any serious problems with drinking.[37] Maintenance of this follow-up cohort over time has been excellent. Only 18% were lost to follow-up by 14 years (primarily because they moved out of the area). At the 7-year examination we saw 95% of the children examined at 4 years, and at the 14-year examination we saw 93% of the children examined at 7 years. Complete weight data for all six examination periods is available on 335 children. The maximum number of children examined in the present analyses is 553, representing all children in the cohort who were seen in at least one of the follow-up examinations. Delivery data on weight, height, and head circumference were abstracted from the medical records of 1439 of the original 1529 mothers interviewed during midpregnancy.[38] Subsequent measurements were obtained during laboratory visits.

The prenatal interview included questions about all medications and other drugs used during pregnancy, smoking and dietary habits, and other life-style and pregnancy history factors thought to relate to pregnancy outcome.[33,36] The quantity-frequency-variability structured interview[39] was given for beverage consumption during two time periods: prior to pregnancy or recognition of pregnancy and during pregnancy. Separate questions were asked for beer, wine, liquor, and cola beverages. The questions about alcoholic beverages yielded a variety of derived scores reflecting variations in level, timing, and pattern of prenatal alcohol exposure. The quantitative scores—average ounces of alcohol per day, number of drinking occasions monthly, average number of drinks per drinking occasion, and maximum drinks on any occasion—all had highly skewed distributions and were log-transformed for analysis. We also included a 5-point scaled alcohol score of quantity-frequency-variability proposed by Cahalan et al.,[39] a binary indicator of drinking five or more drinks on at least one occasion, and an indicator of complete abstinence from alcohol (prerecognition and during pregnancy). Distributions of scores on our 12 primary measures of alcohol exposure (prior to log transformation) are summarized in Table 1 for drinkers only. The precision of these self-report measures is discussed in a previous publication.[37] The correlations among the alcohol measures based on all 553 cases range from .39 to .91. Average daily nicotine use was calculated by multiplying the number of cigarettes smoked per day by the nicotine content of the brand smoked. (The logarithms of the number of cigarettes smoked [+1] and nicotine [+1] are highly correlated in this sample; $r = .85$.)

Analyses and Results

In our sample, in spite of its having been overweighted for heavier drinkers, low-birthweight babies (those weighing less than 2500 g) per se were rare. Our screening sample included 41 infants out of 1437 survivors with birthweights below 2500 g (2.9%). In our follow-up sample, only 12 of 553 infants (2.1%) were below this threshold. By contrast, National Center for Health Statistics standards suggest a low-birthweight incidence of 5% in neonates of normal, healthy, middle-class White mothers,[40] and Day et al. found an incidence of 11% in their low-socioeconomic-status sample.[12]

Our statistical analyses are presented in three stages: (1) simple correlations of alcohol measures with weight, height, and head circumference at six ages from birth to 14 years; (2) covariate adjustment with regression analysis; and (3) individual growth trajectories of specific children.

Simple Correlations

Table 2 presents the correlations of each of our measures of prenatal alcohol dose with the three measures of child size at six ages. Correlations for size measures at delivery are based on slightly larger sample sizes than are the follow-up measures, but the results are little affected by the subjects lost to follow-up.

TABLE 2—Correlations of Measures of Prenatal Alcohol Exposure with Growth through 14 Years of Age

	Delivery	8 mo	18 mo	4 y	7 y	14 y
Weight	(n = 552)	(n = 453)	(n = 485)	(n = 451)	(n = 481)	(n = 452)

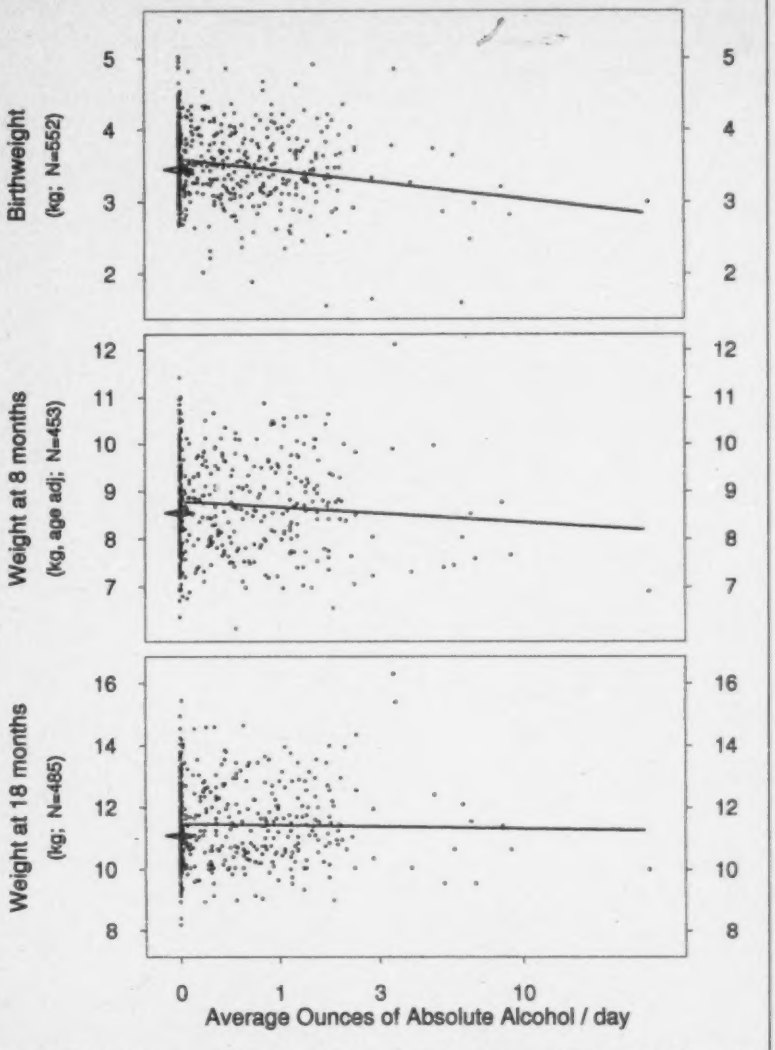
Note. All correlations are unadjusted except at 8 months. A sampling bias, inadvertently introduced into the 8-month data by examining babies of heavier-drinking mothers at a significantly older age, necessitated the use of age-adjusted correlations provided in this column.
[a]Log-transformed scores were used for analysis because of skewed distributions.

The 8-month data have been linearly adjusted for age of the child at the 8-month examination because the children who were examined relatively late (at this examination only) were disproportionately the offspring of heavier drinkers.

At birth, there is a consistent pattern of negative correlation for all dose measures against all three size measures. At 8



Note. The horizontal open diamond superimposed on the vertical row of abstainers in each panel indicates the level of the abstainer effect.

FIGURE 1—Scatterplots of average ounces of absolute alcohol per day prior to pregnancy recognition (AAP), by birthweight (top), age-adjusted weight at the 8-month examination (center), and 18-month weight (bottom).

months this pattern is still apparent, but the magnitude of the correlations is not as strong. After 8 months, the consistency of these signs wholly vanishes. The neonatal size measure having the highest average correlation with this suite of dose measures is birthweight; of the 12 alcohol scores, the one having the highest average correlation with the suite of three size measures is log average ounces of absolute alcohol per day prior to pregnancy recognition (AAP). After birth, only head circumference seems to display any pattern of consistent (although modest) correlation with alcohol, but in this case only for binge-oriented measures such as average number of drinks per drinking occasion and maximum number of drinks per occasion, and only after deletion of or adjustment for abstainers. The resulting correlations with these binge scores remain in the range −.10 to −.12 over the last three examination periods.

Figure 1 presents scatterplots of AAP by birthweight, weight at 8 months, and weight at 18 months. These scatters represent correlations of −.15, −.05, and −.03, respectively, for the three ages as reported in Table 2. The figure displays fitted regression lines computed only for the mothers who drank. Horizontal open diamonds mark the mean weights of the children of abstainers. Correlations for the nonabstainers are −.20, −.09, and −.02, respectively. The effect of alcohol on birthweight is evident whether or not abstainers are included. At 8 months, the smaller alcohol effect is detectable only when abstainers are excluded. At 18 months and beyond, no alcohol effects are evident.

The association suggested by the figure can be summarized by dividing the sample according to four dose ranges calibrated by AAP: the 154 children of abstainers (AAP of 0); the 125 with positive AAP of less than 0.14; the 18 children whose doses were greater than 4.5 drinks per day on average (AAP greater than 2.28; the top 1/32 of the sample); and the remaining 261 children. At birth, the most substantial effect is a contrast of the highest-exposure group with the low-exposure group (excluding the abstainers). The mean weights in grams and standard deviations (SDs) for these four groups, from highest-exposure to abstainers, are as follows: 3184 (795), 3465 (516), 3561 (474), and 3518 (514). At 8 months the most striking dependence of weight upon dose appears to be a nonlinear tail effect, with a decrease in mean weight evident only in the highest-exposure group. The mean weights in grams and standard deviations, from highest-exposure group to abstainers, are now 8386 (1370), 8715 (961), 8632 (985), and 8696 (973). In fact, the offspring of abstainers are slightly lighter in mean weight than the most highly exposed cases at all later ages. We suspect that this effect is not teratological but sociological.

A multivariate analysis of all exposure and outcome variables together was carried out, using nonlinear partial least squares methods described in Sampson et al.[30] This latent variable analysis does not reveal any long-term relationship between overall alcohol exposure, represented as a composite linearized dose measure, and child size taken across the lifespan from birth to 14 years. The multivariate analysis thus supports the data from the table of simple correlations (Table 2). Prenatal alcohol shows its strongest relationship with birthweight; is still associated with 8-month weight, although the magnitude of the effect is smaller; and rapidly falls to the noise level by 18 months. This phenom-

enon (the vanishing of a correlation with size over time) is a likely consequence of what is normally referred to as "catch-up growth." The correlations of dose with changes in weight are in accordance with what one expects from the correlations wave by wave and supply no additional insights.

Covariate Adjustment

A wide variety of factors correlate with birthweight (cf. Goldstein[41]). In Table 3 we display correlations of a variety of well-known determinants of child size against the six outcome measures for weight. (Tables of correlations with the height and head circumference measures are similar.) Most predictors fall into two groups: those having effects that remain substantial over time (e.g., sex and maternal size measures) and those having correlations with size that quickly fall to zero after birth (e.g., alcohol, nicotine, marijuana, and prematurity).

In extensive multiple regression analyses not reported here, all the variables presented in Table 3 were considered in assessments of the significance of prenatal alcohol exposure as a predictor of child size. Most models used log AAP as the primary predictor of size because it is the alcohol measure of highest average correlation with all the birth size measures. In these regressions, child size was primarily predicted by maternal size (height, pregnancy weight, and weight gain during pregnancy) and sex of the child. None of the nicotine, marijuana, and alcohol scores were reliable predictors of child size after 8 months. These conclusions were unchanged when the least significant terms were dropped from the regression models. In addition, these conclusions were unaffected by optimally transforming the alcohol scores (as in Sampson et al.[30]) or by replacing them with a composite, such as a latent alcohol variable reflecting the joint impact of all the measured dimensions of alcohol dose represented in the 12 prenatal alcohol scores.

Regression analyses using the binge alcohol measures, which correlate best with postnatal head circumference, show similar results: consistently modest, but not significant, estimated effects on head circumference, as suggested by the simple correlations in Table 2.

Individual Growth Trajectories

Separately for each size measure, we considered the babies who were among the lowest 15% on that measure and among the top 15% on AAP. There were 19, 15, and 11 babies who met the criteria for weight, length, and head circumference, respectively. Even these low-birth-size/heavier-exposure babies, in general, showed increased catch-up growth on height, weight, and head circumference, relative to the rest of the cohort, after 8 or 18 months. Infants selected only for extreme size demonstrated, on average, a similar degree of catch-up growth, or what might be called "regression to the mean."

We also examined growth trajectories across time for the three children in this study who were diagnosed with fetal alcohol syndrome by dysmorphologists (two at birth[42] and one, who was not examined at birth, at 4 years[43]). As growth deficiency is one of the characteristics of fetal alcohol syndrome, one would not expect catch-up growth in persons with this diagnosis, at least until the onset of puberty. But neither of the two children diagnosed with the syndrome at birth was excessively low in birthweight. One was more than 2 standard deviations below our sample mean for length, and both were near −2 standard deviations for head circumference. Even these children with a clinical diagnosis of fetal alcohol syndrome showed increasingly normal weight and height over time. Head circumference was more consistently low. The three children with clinical fetal alcohol syndrome showed a continued postnatal decrement in head circumference, relative to the rest of the sample, through 8 to 18 months of age.

TABLE 3—Correlations of Prenatal Demographic Characteristics and Covariates with Weight through 14 Years of Age

	Delivery	8 mo	18 mo	4 y	7 y	14 y

Log nicotine	−.26	.00	.04	.04	.05	.10
Log marijuana	−.17	−.03	−.04	−.08	−.01	.07
Log alcohol (prior to pregnancy recognition)	−.15	−.05	.03	.01	.01	.05

Note. Data in this table were tabulated from the maximum number of subjects seen for each exam period, including abstainers (maximum sample size = 553). See Streissguth et al.[30,39] for a full description of measurement of covariates.

Discussion

Dangers of Overreliance on Multiple Regression in Teratology Studies

This paper is the third recent report of alcohol effects on growth (neonatal and postnatal) based on prospective longitudinal studies of prenatal alcohol exposure. Our finding of a significant but transient effect of alcohol upon child's size is in apparent agreement with the conclusions of Greene et al.[13] and in apparent disagreement with those of Day and colleagues.[12,22–24] Both of these other studies use additional measures of alcohol exposure in the third trimester, data that were not gathered in the present study owing to budgetary constraints. However, as the two studies using such third-trimester data disagree with each other, our not having such exposure data is not likely to account for discrepancies be-

tween our findings and theirs. Rather, we would emphasize differences in study design and statistical data analysis between the studies as contributors to the differences in reported results.

The papers by Greene et al. and Day et al. do not report any simple correlations between alcohol dose and outcomes. We therefore cannot tell whether the regressions are "creating" an effect that was not apparent previously or whether they are improving the precision of an estimate of an effect for which there is already evidence. Greene et al. used a backward selection procedure on covariates,[13] whereas Day et al. used forward selection procedures with blocks of variables.[12,22-24] Regression coefficients (and their associated *P* values) computed from hierarchical stepwise procedures can vary greatly over the steps of the procedure in a manner that depends strongly on the joint distribution of all the predictors.[44]

Consider, for example, in Table 2, the unadjusted zero-order correlation of approximately −.05 between 8-month weight and average ounces of alcohol per day prior to pregnancy recognition. A zero-order correlation of −.05 becomes a more negative beta (regression coefficient) when covariates are included that are either positively correlated with both alcohol and 8-month weight or negatively correlated with both alcohol and 8-month weight. Inclusion of an indicator for abstainers confirms a recognized abstainer effect on birthweight, albeit at a lower level, that has been reported by Little,[2] discussed at length by Little and Wendt,[45] and most recently detected again in the EUROMAC study.[46] Linear adjustment principally for one other covariate, log parity, results in a nominally significant regression coefficient for log AAP (partial correlation $\approx -.10, P < .05$). Other highly significant correlates of 8-month weight—sex of child, maternal height, and gestational age—serve only to slightly lower the standard error of the regression coefficient. Inclusion of one additional term, log uses of marijuana, would render the coefficient for alcohol's effect on 8-month weight again insignificant at the nominal .05 level.[47] Thus, although there is evidence of effects of prenatal alcohol exposure on size lasting to 8 months, the reasonably stable significance of the effect of alcohol on birthweight is largely lost.

Our criticisms of the reporting of multiple regression analyses may be summarized in a general problem. The use of multiple-regression methods to search for true effect estimates is much less reliable than their use in searching for optimal predictions (see Mosteller and Tukey[44]). The purposes of covariate analysis in observational studies are two: to adjust for bias and to sharpen the precision of an estimated effect.[48] It is critically important to understand to what extent a regression adjustment appears to present an adjustment for bias and to what extent it simply explains variability in the response and so lowers the estimated variance of a regression slope.

Covariates do not always have enough leverage to substantially improve the precision with which an (alcohol) effect can be estimated, and those that have such leverage, such as socioeconomic status in many studies, ordinarily are not scaled coherently enough to predict the outcome linearly without interaction. That is, in observational studies the attempt to increase the precision of a beta (regression coefficient) inexorably introduces bias as well. As the two purposes of covariate adjustment cannot be disentangled, both must be viewed with suspicion. Multiple regression is safely used primarily as a check that alcohol coefficients are not biased. The disagreement between the conclusions of Greene et al.[13] and those of Day et al.[12,22-24] may serve as a useful caution in this regard: similar analyses of similar outcomes similarly adjusted for similar covariates may result in different findings.

The closer a sampling design can come to a planned experiment, the more stable and reliable the resulting regression slopes. Thus low-dose teratogenic effects can rarely be estimated effectively from samples of convenience, no matter how strenuously one considers covariates. Once a representative sample is enriched by stratified oversampling, as ours was, further oversampling of high doses only increases the precision with which the dose–response relationship can be calibrated; it does not substantially alter the slope of the relationship per se. The longitudinal studies of Greene et al. and Day et al. also oversampled the heavier-drinking ends of their target populations.[13,23,24]

Alcohol Effects on Growth and Comparisons with Functional Outcomes

Our finding that the correlations of alcohol dose with our size measures drop to zero in early childhood is not evidence that the physical effects of prenatal exposure have ceased by that time. We find, for instance, that our composite prenatal dose measure correlates with puberty status at age 14 years. (This will be the topic of another paper.) The effect of alcohol on birthweight we have found here is supported, of course, by studies further oversampling the high-dose range, such as studies of children of alcoholic mothers.[49-51] The absence of a finding for later size is owed to the fact that a broad range of genetic and environmental factors influence size. In contrast, the enduring effects of prenatal alcohol exposure are clear when measured more sensitively in terms of neurobehavioral and/or functional outcomes.[29-34]

Another observation from our analysis pertains to current public health concerns about protocol for fetal alcohol syndrome screening. We noted that of the three children diagnosed with fetal alcohol syndrome, two were small at birth but exhibited typical catch-up growth in weight. The third, although within the normal range of birth size, was very small by age 4, when he was diagnosed. His size deficit persisted thereafter. (This child did not receive a neonatal dysmorphology examination, as his examination was superseded by a birth the same day of a more heavily exposed baby.)

Although a clinical dysmorphology examination detected these offspring with fetal alcohol syndrome, none of their actual birthweights (2840, 2980, and 3140 g) was more than 1 standard deviation below the mean according to usual growth curves, nor would these children technically be classified as having intrauterine growth retardation. Nevertheless, their deviant pattern of increasingly discrepant head circumference up through 8 or 18 months (previously detected in a 10-year follow-up of the original children diagnosed with fetal alcohol syndrome[52]) seems indicative of their underlying central nervous system dysfunction during this period of continuing brain growth.

The discrepant childhood size trajectories of these three children with fetal alcohol syndrome also have important public health implications. The fact that many persons with fetal alcohol syndrome or fetal alcohol effects end up as unusually small adults[53,54] is not helpful in constructing protocols for diagnosis if the onset of this shortfall of size is as variable in time as it was for these three children. Growth deficiency in offspring is one possible consequence of maternal alcoholism. It does not appear to be satisfactory as a unitary screening criterion of fetal alcohol

syndrome, either at birth or at any other age.

Birthweight is far too multifactorial an indicator of generalized fetal suboptimality to serve as a useful outcome for any subtler studies of early developmental processes and their consequences. For instance, earlier research on this same cohort of children demonstrated a substantial association of alcohol dose with a pattern of neurobehavioral deficits at age 7 years.[29-31] But infant size is not a significant covariate of the neuropsychological behaviors we found to be correlated with prenatal alcohol exposure. Thus, even though birth size and 7-year neurobehavioral deficits each appear to show effects of alcohol dose, the birth size deficit is not predictive of the later neurobehavioral deficit. This might be because the aspects of dose (i.e., timing and variability) that are most salient for birth size are different from the binge-oriented measures most salient for later behavioral deficits.[30,31] We are, by and large, not looking at babies of very low birthweight, and the aspects of psychomotor development correlated with low birthweight do not appear to be the aspects that are well correlated with prenatal alcohol exposure. In our sample, low birth size is not a mediator of later alcohol-related problems, nor does it correlate with dose at the extremes of the dose range, nor is it even a predictor of continuing small size. Our study thus strongly suggests that the role of size measures in epidemiologic teratology studies may be overrated.

Conclusions

It is likely that the multifactoriality of birthweight accounts for the inconsistency of alcohol's putative effects on birthweight in the range of studies we reviewed in the Introduction. The effect of alcohol on birthweight, although really there (i.e., it is reliable and stable in stratified samples), can be swamped by other effects—nicotine, race, maternal age, socioeconomic status—some of which are quite a bit more difficult to calibrate, so that the published estimate of the alcohol effect is a function of the range of the covariates and the precise details of the regression technology chosen. Effects of alcohol are much more clearly delineable on outcome measures that are *not* consequences of these other factors of intrauterine growth retardation—outcomes such as aberrant profiles on intelligence tests, speed of information processing, or various subtle but crucial features of vigilance and attention in elementary and junior high school years.

Much of the current public policy debate about the effects of moderate prenatal alcohol exposure has centered on effects as exemplified by birthweight decrements. We believe this emphasis is unfortunate. Although lowered birthweight, with the concomitant risk of intrauterine growth retardation, is clearly of great relevance to public health, its dependence on prenatal alcohol exposure is both quite a bit less sensitive than the dependence of other outcomes we have studied and also much less enduring. The transience of the effect of subextreme alcohol exposure on birthweight appears to be little different in principle from that of nicotine or indicators of mild undernutrition; all these effects vanish over the course of the first few postnatal months (in our analyses). In contrast to effects on size measures, the teratogenic effects of alcohol on certain neurobehavioral sequelae appear to last as long as we have followed our subjects—through 14 years, in the most recent analyses[33,34]—and not only in laboratory testing, but in the classroom as well.[32] □

Infertility in Women and Moderate Alcohol Use

ABSTRACT

Objective. The purpose of this study was to investigate the relationship between moderate alcohol intake and fertility.

Methods. Interviews were conducted with 3833 women who recently gave birth and 1050 women from seven infertility clinics. The case subjects were categorized based on the infertility specialist's assignment of the most likely cause of infertility: ovulatory factor, tubal disease, cervical factor, endometriosis, or idiopathy. Separate logistic regression models were used to assess the relationship between alcohol use and each type of infertility, adjusted for age, infertility center, cigarette smoking, caffeine use, number of sexual partners, use of an intrauterine device (for tubal disease), and body mass index and exercise (for ovulatory factor).

Results. We found an increase in infertility, due to ovulatory factor or endometriosis, with alcohol use. The odds ratio for ovulatory factor was 1.3 (95% confidence interval [CI] = 1.0, 1.7) for moderate drinkers and 1.6 (95% CI = 1.1, 2.3) for heavier drinkers, compared with nondrinkers. The risk of endometriosis was roughly 50% higher in case subjects with any alcohol intake than in control subjects (OR = 1.6, 95% CI = 1.1, 2.3, at moderate levels; OR = 1.5, 95% CI = 0.8, 2.7, at heavier levels).

Conclusions. Moderate alcohol use may contribute to the risk of specific types of infertility. (*Am J Public Health.* 1994;84:1429–1432)

Introduction

Although as many as 20% of married women in the United States have experienced infertility during their lifetime,[1] little attention has been given to the effect that many common exposures, including exposure to alcohol, have on a woman's ability to reproduce.

Much of the research that has been conducted involves studies of animals or alcoholic women. The animal research indicates that decreased steroid hormone levels,[2] reduced ovarian weight,[2,3] and amenorrhea[3] result from alcohol administration to rats or monkeys. Becker et al. reported that alcoholic women experienced higher frequencies of menstrual disturbance, abortion, and miscarriage than control subjects.[4] In a national survey of alcohol use habits and reproductive dysfunction in 917 American women, menstrual problems and gynecologic surgery were increased in women who reported high levels of alcohol intake.[5]

In this study, we examined the effect of moderate alcohol use on fertility in women. We compared self-reported history of alcohol consumption in case subjects who had primary infertility with that of control subjects who recently gave birth.

Methods

Originally, this case–control study was undertaken from 1981 through 1983 to examine the relationship between contraceptive practices and a woman's ability to conceive.[6,7] Case subjects were drawn from women who attended seven infertility clinics in the United States and Canada and who were accepted for work-up and evaluation. Infertility was defined as the inability to conceive after 12 months of unprotected intercourse or the failure to deliver a live-born child.

Case subjects were excluded if their infertility was due to congenital abnormalities, if they were seeking reversal of tubal ligations, or if their husbands had had vasectomies. Among the total number of case subjects who were eligible for interviewing, 5% refused, 10% were not interviewed due to a language barrier or other problem, 10% were lost to follow-up, and 10% had not completed their infertility work-up by the close of the study, leaving 1880 case subjects who were included. Work-ups in these subjects identified the following causes of infertility: ovulatory factor, tubal disease, cervical factor, endometriosis, male factor, or idiopathic infertility. Diagnostic protocols included, when indicated, measurement of basal body temperatures, hormonal studies, endometrial biopsies, postcoital test, hysterosalpingography, and diagnostic laparoscopy.

We assigned each woman to one infertility category based on her most likely cause of infertility, as indicated by the evaluating physician, and designated this cause as the case subject's "first diagnosis." However, infertility is often a multifactorial disorder. In a previous publication, we described in detail the distribution of second diagnoses (accom-

panying disorders that may have contributed to the infertility) among the women in each diagnostic category.[8] The group with ovulatory factor had the lowest percentage of women with an additional disorder (14.2%), whereas the group with a first diagnosis of tubal disease had the highest percentage (26.5%). Idiopathic infertility was always designated as a first and only cause.

Control subjects were recruited from women admitted for delivery of a live birth at hospitals adjacent to the infertility clinics. Adjacent hospitals were used to ensure both that the control subjects would have sought care at the hospital infertility clinic if they had been infertile and that the case subjects would have delivered at the hospital if they had become pregnant. All women admitted for delivery were eligible to be control subjects; among the potential control subjects, 5% refused to be interviewed, 8% had undergone infertility therapy, and 5% were not interviewed because of a language barrier or poor condition of the mother or infant, leaving 4023 control subjects for whom interviews were completed.

This report focuses on the 3833 White control subjects and 1050 White case subjects with no live-born children whose first diagnosis was ovulatory factor, tubal disease, cervical factor, endometriosis, or idiopathic infertility.

Information concerning reproductive history, medical and surgical history, and personal habits was collected by personal interview. Interviews of all case subjects were conducted before their infertility diagnosis. To ensure that all exposure information referred only to the time period before the likely onset of infertility, an "index date" was calculated for each case subject by subtracting the number of months during which she had been trying to conceive from the date on which she had first consulted an infertility specialist. Because the event that distinguished case subjects with primary infertility from control subjects was the first live birth, the index date for each control subject was the estimated date of conception of the first live-born child. If the control subject's pregnancy was planned, the index date was defined as the time at which the couple began attempting conception. Only exposures that occurred before the index date were considered relevant.

During the interview all subjects were asked "what was your average weekly consumption of each of the following beverages: beer (cans per week), wine (glasses per week), and liquor (ounces per week)" before the index date. To determine total alcohol intake per week, 13 g of alcohol was assigned per can of beer, 11 g per glass of wine, and 15 g per ounce of liquor.[9] Women consuming 100 g or less of alcohol per week (approximately one drink or less per day) were considered "moderate" drinkers, whereas those drinking more than 100 g per week were categorized as "heavier" drinkers.

Adjusted odds ratios (ORs) and 95% confidence intervals (CIs) for each level of alcohol intake were calculated by using multiple logistic regression.[10] Separate models were used for each type of infertility. Variables evaluated included age, infertility center, religion, education, body mass index (weight in kilograms/height in meters squared), exercise, cigarette smoking, number of sexual partners, type of contraceptive used, and caffeine intake. Because the study included few non-White women, the analysis was restricted to Whites to control for race as a potential confounder. In all of the final models, age (<25, 25–29, 30–34, >34 years), center (Boston; Vermont; Quebec; Washington, DC; Kentucky; Colorado), cigarette smoking (current, former, never), number of sexual partners (1, 2–5, >5), and caffeine consumption (0–3.0, 3.1–5.0, 5.1–7.0, >7.0 g/week) were included. For analyses of tubal disease, we also controlled for use of an intrauterine device (yes or no); body mass index (<19.0, 19.0–20.9, 21.0–22.9, >23.0 kg/m^2) and exercise (0, 1–6, >6 h/week) were controlled for in models of ovulatory factor.

All tests of significance of the odds ratio were two-tailed. For the analyses involving tests of trend, we categorized alcohol use as explained above, assigned scores to each level of intake, and treated the scored factor as a continuous variable in the logistic regression model. All significant associations were indicated by $P \leq .05$ or a 95% confidence interval excluding 1.

Results

In general, with the exception of women with an ovulatory factor, case subjects tended to be somewhat older than control subjects (Table 1). Educational status was similar in the case and control groups, although those with tubal disease were slightly less educated than control subjects. Similarly, cigarette smoking and sexual habits were comparable in all women, but case subjects with infertility due to tubal disease or cervical factor were more likely to be smokers and to have had multiple sexual partners than were control subjects.

Case subjects who were diagnosed with tubal disease reported the highest levels of alcohol intake. Those with ovulatory factor, cervical factor, or endometriosis also consumed more alcohol than control subjects, although the majority of women in all of the groups reported no alcohol use.

After we adjusted for risk factors, significantly increased odds ratios were observed for infertility due to a first diagnosis of ovulatory factor or endometriosis (Table 2). For ovulatory factor, the odds ratio was 1.3 (95% CI = 1.0, 1.7) for moderate drinkers and 1.6 (95% CI = 1.1, 2.3) for heavier drinkers compared with nondrinkers. This trend of increasing risk of ovulatory infertility with increasing alcohol consumption was statistically significant (test for trend, $P = .005$). There was also a similar trend among women diagnosed with cervical factor (OR = 1.3, 95% CI = 0.8, 2.1 for moderate drinkers; OR = 1.6, 95% CI = 0.8, 3.3 for the heavier drinkers); however, relatively few women with cervical factor reported using alcohol and these estimates were thus unstable. The odds ratio for endometriosis was 1.6 (95% CI = 1.1, 2.3) for moderate drinkers and 1.5 for heavier drinkers (95% CI = 0.8, 2.7) compared with women who did not drink.

Approximately 4% of case subjects with a first diagnosis of an ovulatory factor also had endometriosis, and 12% of those with endometriosis as a first diagnosis were found to have an ovulatory dysfunction. To examine whether the presence of women with both an ovulatory factor and endometriosis had an effect on the risk of infertility observed in these two diagnostic groups, the data were reanalyzed after removing women with both diagnoses (Table 2). The risk of an ovulatory factor associated with alcohol use remained the same (OR = 1.3 for women drinking moderately and OR = 1.6 for those drinking more heavily), whereas the risk increased slightly in women with endometriosis (from an OR of 1.6 to 1.7 at moderate levels and from an OR of 1.5 to 1.8 at higher levels).

TABLE 2—Case Subjects' Risk of Infertility, by Alcohol Use and Type of Infertility

Infertility Type	Moderate Alcohol Use OR[a]	Moderate Alcohol Use 95% CI	Heavier Alcohol Use OR[a]	Heavier Alcohol Use 95% CI
First diagnosis				
Ovulatory factor[b] (n = 431)	1.3	1.0, 1.7	1.6	1.1, 2.3
Tubal disease (n = 230)	1.0	0.7, 1.4	1.2	0.7, 1.9
Cervical factor (n = 105)	1.3	0.8, 2.1	1.6	0.8, 3.3
Endometriosis[c] (n = 180)	1.6	1.1, 2.3	1.5	0.8, 2.7
Idiopathic (n = 104)	0.9	0.5, 1.4	0.7	0.3, 1.6
Ovulatory factor, excluding women with the additional diagnosis of endometriosis (n = 413)	1.3	1.0, 1.7	1.6	1.1, 2.4
Endometriosis, excluding women with the additional diagnosis of ovulatory factor (n = 158)	1.7	1.2, 2.5	1.8	1.0, 3.2

Note. OR = odds ratio; CI = confidence interval.
[a]Adjusted for infertility center, age, number of sexual partners, cigarette smoking, and caffeine intake. For ovulatory factor, hours of vigorous exercise and body mass index were included as confounders; for tubal disease, intrauterine device use was included. Women who reported no alcohol use were used as the reference group.
[b]Test for trend: $P = .005$.
[c]Case subjects who were diagnosed with endometriosis before their infertility evaluation and control subjects who reported a history of endometriosis were excluded.

Discussion

This study demonstrates an association between reported consumption of alcohol and infertility due to ovulatory factor or endometriosis. A small, but significantly increased, risk of ovulatory infertility was observed for women reporting moderate alcohol intake, whereas this risk rose considerably in those women drinking at heavier levels compared with nondrinkers. Increased risks of endometriosis were found at both levels of alcohol intake examined.

Several limitations of these data need to be considered. Because information on exposure history was obtained by self-report, misclassification of alcohol use may have occurred. In particular, approximately 50% to 60% of the women in the case and control groups reported no alcohol intake, slightly more than the 48.3% of women in a national survey of drinking and reproductive dysfunction.[5] To minimize information bias, data were collected during personal interviews that were conducted by trained nurses. Although we were not able to verify the self-reported alcohol use in this population, Willett et al. found that self-report of alcohol intake was highly reproducible in a study of 173 women (Spearman correlation coefficient = 0.90).[11] Our study population was composed exclusively of women of relatively high socioeconomic status, as indicated by the large majority of college-educated participants (approximately 70%). It is possible that their alcohol intake was lower than that of the general population, although to our knowledge no pertinent data have been published. Although this issue may affect the generalizability of our results, it would not affect the validity of our comparison of alcohol intake in case and control subjects, because several measures indicate a similar socioeconomic status in the two groups (education, cigarette smoking, and number of sexual partners were comparable).

This similarity is particularly important in a study such as this one, because the case subjects were recruited from women referred to a specialized medical clinic. Such women may be different, particularly with respect to socioeconomic status, even from the "typical" hospital patient. And alcohol intake could vary with social class. However, as we noted, several socioeconomic indicators are similar among the case and control groups here. In addition, the total household income was similar for case and control subjects, with approximately 50% of both groups falling into the highest income category, suggesting a lack of referral bias in this study.

An additional bias could have resulted from the fact that all the case

subjects were attempting their first pregnancy, whereas some control subjects were multiparous and had to recall exposures before their first pregnancy. In fact, the recall period (i.e., the mean difference between the index date and the interview date) was similar for both groups (approximately 3 years). Although it is possible that subjects' recall of alcohol use 3 years in the past may not have been completely accurate, the recall period was similar for case and control subjects; thus, any potential bias would be nondifferential and lead to an underestimation of the actual risks of infertility associated with alcohol use.[12]

Although the control subjects were instructed to report alcohol use before their first pregnancy, their more recent intake could have been reflected in their report. We reanalyzed the data for the primiparous control subjects only (approximately 50% of the control group) and found risk estimates corresponding to those obtained with the entire control group: for ovulatory factor, the OR was 1.1 (95% CI = 0.9, 1.5) for moderate alcohol use and 1.6 (95% CI = 1.0, 2.6) for heavier alcohol use; for endometriosis, the OR was 1.3 (95% CI = 0.9, 1.9) for moderate intake and 1.4 (95% CI = 0.7, 2.6) for heavier intake.

Still, all the control subjects would have been advised to abstain from alcohol during pregnancy, perhaps leading to an underreport of their alcohol use. If this underreporting were true, we would expect to see increased alcohol intake among all the case subjects. Alcohol was associated with an increased risk of ovulatory factor, cervical factor, and endometriosis; but there was little risk of tubal disease among alcohol users, and a slightly decreased risk of idiopathic infertility was observed.

Because infertility is often a multifactorial disorder, it is also possible that the increased risks of infertility associated with a first diagnosis of ovulatory factor or endometriosis were due to the presence of women with both of these diagnoses. However, when we removed women from each group who were diagnosed with both disorders, a reanalysis of the data did not lead to any appreciable change in the results.

There may be a biological basis for the association that we observed between alcohol use, ovulatory infertility, and endometriosis. Research on the chronic effects of alcohol use on menstruation indicates that alcoholism is associated with early menopause[13] and reduced levels of follicle-stimulating hormone,[13,14] although it remains unknown whether these consequences would also result from the more moderate levels of alcohol use reported in this study. In a cross-sectional study of drinking and reproductive dysfunction, heavy menstrual flow and dysmenorrhea were associated with moderate and high levels of alcohol intake.[5] Both of these factors have been related to an increased risk of endometriosis.[15]

It is possible that women with symptoms of endometriosis (specifically, pain in the pelvic area) drink alcohol to help alleviate their pain. However, when we examined use of alcohol by the case subjects with endometriosis, we found no significant difference between women reporting none to mild dysmenorrhea and those reporting moderate to severe dysmenorrhea. Approximately 50% of case subjects in both those groups were alcohol users.

There is presently little information available on the specific effects of moderate alcohol intake on reproductive capacity. This is one of few investigations that has examined the consequences of moderate alcohol use on distinctive types of fertility problems. We found the largest effect of alcohol use to be on the hormonally associated fertility disorders. It is of interest that an increased risk of breast cancer has also been associated with moderate alcohol use.[16,17] No mechanism has been established yet to explain this association, but breast cancer is most likely an estrogen-dependent neoplasm,[18] and both ovulatory function and endometriosis are related to estrogen levels. □

Trends in the US Prevalence of Drug-Using Parturient Women and Drug-Affected Newborns, 1979 through 1990

Marvin Dicker, PhD, and Eldin A. Leighton, PhD

ABSTRACT

Objectives. There has been a lack of reliable national data on the number of pregnant women using drugs and the number of newborns affected by such use. The major reasons for this lack have been inadequate sampling and data collection procedures and the lack of a risk assessment perspective in analysis. This paper corrects for these inadequacies.

Methods. Data from 1979 through 1990 from the National Hospital Discharge Survey, an annual survey by the National Center for Health Statistics, were analyzed.

Results. Between 1979 and 1990 there was a 576% increase in the rate of discharges of drug-using parturient women in the United States and a 456% increase in the rate of discharges of drug-affected newborns. After adjustment for underreporting, a "best estimate" of the number of discharges from 1988 through 1990 was about 88 000 per year for drug-using parturient women and about 48 000 per year for drug-affected newborns.

Conclusions. Although the data support the occurrence of a national epidemic of drug use among pregnant women during the 1980s, the size and severity of this epidemic have been overstated. (*Am J Public Health.* 1994;84:1433–1438)

Introduction

Although much has been written about an epidemic of drug use among pregnant women in the United States during the 1980s, two recent research papers have noted that there have been almost no reliable national data on the prevalence or incidence of such use in particular years or on the nature of the historical trend associated with such use.[1,2] National data on the use of drugs by pregnant women is of special interest because of the effect drug use might have on the health of women and their newborns. The lack of reliable national data has made it difficult to estimate both the extent and seriousness of the national problem and the amount of medical and other societal resources needed to deal with the problem.

This lack of national data was partially corrected in a 1991 paper in which we used data from the National Hospital Discharge Survey (NHDS) to examine the historical trend in diagnosed drug-related births in US hospitals between 1979 and 1987.[3] Of all the recent studies of drug use affecting newborns, this is the only study with both a representative national sample and reliable data collection techniques. This study found a 339% increase between 1979 and 1987 in the estimated discharge rate for newborns with a drug diagnosis. However, after adjustment for underreporting, the absolute number of newborns with a drug diagnosis in 1987 was estimated to be about 38 000—an estimate that was much smaller than others reported in the literature. In this paper we expand the previous study by presenting data extending the historical trend for drug-affected newborns to 1990.

We also present data on the historical trend between the years 1979 and 1990 for the US population of pregnant women diagnosed as using drugs at the time they entered the hospital for delivery. These women will be labeled "drug-using parturient women" to distinguish them from the larger population of pregnant women who used drugs at some time during their pregnancy.[2] The data on parturient women are from the same set of annual surveys used for our previous study of drug-affected newborns;[3] however, the data on newborns and the data on parturient women were collected independently of one another within each annual survey. This means that information about a mother cannot be linked to information about her child. As a result, each annual estimate of the number and rate of drug-using parturient women is an independent estimate of the number and rate of drug-exposed newborns.

Methods

Data Sources

Data for the present study are from the NHDS, which is conducted annually in the United States by the National Center for Health Statistics (NCHS). Survey responses were analyzed from public use files for the 12 years 1979 through 1990. This survey uses a stratified probability sample and weights to pro-

TABLE 1—Diagnostic Codes Used in Study

Description of Diagnosis	ICD-9-CM Code(s)[13]
General	
Drug psychoses	All 292's
Drug dependence	All 304's
Nondependent abuse of drugs	305.2–305.9
Polyneuropathy due to drugs	357.6
Pregnancy and birth	
Drug dependence complicating pregnancy	648.3
Suspected damage to fetus from drugs	655.5
Narcotics/hallucinogens affecting fetus/newborn	760.72, 760.73
Drug withdrawal syndrome in newborn	779.5
Poisoning	
Poisoning by analgesics	965.0, 965.8, 965.9
Poisoning by sedatives and hypnotics	967.0–967.6, 967.8, 967.9
Poisoning by other central nervous system depressants	968.0, 968.5
Poisoning by psychotropic agents	969.0–969.9
Poisoning by central nervous system stimulants	970.0–970.9
Adverse effects of drugs properly used in therapy	E935.0–E935.2, E937–E940

duce national estimates of all discharges from the approximately 6000 nonfederal short-stay hospitals in the United States. As these hospitals account for more than 99% of all births occurring in the United States,[4,5] very few births are not represented in the sample. Overall details of the NHDS's data collection, sampling, and coding strategies can be found in annual reports published by NCHS[6] and in a recent paper by Shimizu.[7]

NCHS redesigned the sample in 1988. Therefore, differences in NHDS estimates between 1987 and 1988 could result from sampling changes rather than changes in hospital utilization. In this study, however, we found no statistically significant differences between the years 1987 and 1988, so the sampling change does not present a problem when interpreting the overall trend presented here.

As stated above, the NHDS uses a complex, stratified sampling scheme. Therefore, to avoid confusion, all national data in the text and tables of this paper attributed to the NHDS are weighted population estimates unless otherwise stated. The number of sample cases underlying each drug-related estimate is found in the footnotes to the tables.

Statistical Techniques

NCHS has established reliability guidelines for using survey results from the NHDS.[6,8,9] To comply with these guidelines, sample cases in this study were aggregated over several years when necessary to create groups of sample size greater than or equal to 30 for newborns and greater than or equal to 60 for parturient women. However, because of the sample redesign referred to above, data for the years before 1988 were never combined with data for 1988 and later years. For combined time periods, the estimate given is an annual average estimate for each year included in the time period.[6,8–11]

Research on the incidence of drug use during pregnancy has focused on the number of cases rather than on rates. The number of cases allows for estimates of the costs or amount of resources needed to deal with problems associated with drug use during pregnancy. However, rates are more useful for assessing such relationships as changes over time, differences between populations, and differences between studies, because rates standardize for differences in population size. Here we present estimates of both numbers and rates. All differences between estimates discussed in this paper are statistically significant ($P < .05$) as determined by a multiple t test based on the Bonferroni inequality.[12]

Identification of Drug Users

Table 1 lists the diagnostic categories considered to indicate a drug-affected newborn or drug use by a parturient woman. A discharge was coded as drug-related if one or more of these *International Classification of Diseases*, Ninth Revision, Clinical Modification[13] (ICD-9-CM) diagnoses was found on the discharge record. However, not all the diagnostic categories listed were actually found.

The types of ICD-9-CM codes selected to identify drug-related discharges can affect both the shape of the historical trend and the total number of cases found. This study follows Rice and Kelman in including E-codes in the set of identifying codes.[10] E-codes indicate adverse effects associated with drugs used properly in treatment. They are included here on the assumption that some physicians may have substituted E-codes for other, more stigmatizing, drug codes when recording drug diagnoses. As this inclusion expands the universe for identifying drug discharges, this paper presents a worst-case scenario in its estimates of the total number of drug-related discharges at any given time.

Results

Drug Use among Parturient Women

Table 2 shows the historical trend in the United States in the estimated average annual number and rate of discharges for drug-using parturient women for the whole decade of the 1980s. The results shown in this table indicate that there was a continuing increase in these numbers and rates during this time. For example, the average annual number of discharges involving drug-using parturient women increased by 624%, from 3799 discharges in the 1979 through 1981 time period (95% confidence interval [CI] = 2389, 5209) to 27 506 discharges in 1990 (95% CI = 23 062, 31 950). The average annual discharge rate also showed a large increase (576%) over the 12 years examined, rising from 10.1 discharges per 10 000 parturient women in the 1979 through 1981 time period to 68.3 in 1990.

Although the impression given by Table 2 is of an alarming continuous increase in the number and rate of discharges for drug-using parturient women during the 1980s, this rate of increase was continuously diminishing. The rate of increase in the number of discharges for drug-using parturient women between the 1979 through 1981 and 1982 through 1984 time periods was 102% (a doubling of the number). This rate of increase dropped continuously throughout the decade until, finally, between 1989 and 1990, the number of discharges for drug-using parturient women decreased by 13%. These statistics demonstrate that drug use by parturient women was increasing at a slower rate throughout the decade, so that by the 1988 through 1990 time period a leveling

TABLE 2—Estimated Number and Rate of Discharges of Parturient Women with a Drug Diagnosis from Nonfederal Short-Stay Hospitals: United States, 1979 through 1990

Year of Discharge	Average Annual No. of Parturient Women		SE for Drug Discharges	Estimated Range of the No. of Parturient Women with a Drug Diagnosis		Rate per 10 000 Parturient Women	Increase in Annual Average No. from Previous Time Period, %
	Total	With a Drug Diagnosis		Low	High		
1979–1981	3 773 719	3 799	719	2 389	5 209	10.1	NA
1982–1984	3 924 429	7 664	870	5 959	9 369	19.5	102
1985–1986	3 808 084	14 536	1 199	12 186	16 886	38.2	90
1987	3 910 926	19 597	1 703	16 259	22 935	50.1	35
1988	3 780 654	28 375	3 567	21 385	35 365	75.1	45
1989	3 936 703	31 706	4 255	23 367	40 045	80.5	12
1990	4 025 456	27 506	2 267	23 062	31 950	68.3	-13

Note. Years were combined to meet National Center for Health Statistics (NCHS) reliability guidelines. Sample sizes for parturient women with a drug diagnosis were as follows: for 1979–1981, n = 68; for 1982–1984, n = 121; for 1985–1986, n = 131; for 1987, n = 98; for 1988, n = 237; for 1989, n = 315; for 1990, n = 247. A discharge was counted as a drug-diagnosis discharge if any of up to seven diagnoses on the discharge record was a drug diagnosis. Standard errors were estimated as follows: before 1988, from charts in the National Hospital Discharge Survey (NHDS) annual summaries[6]; after 1988, from empirical equations in the documentation accompanying the public use tapes. The "low" and "high" estimates are based on 95% confidence intervals.

off had occurred in the number and rate of discharges.

A Comparison of Parturient Women and Newborns

The historical trend. The number of drug-using parturient women may be considered a surrogate measure for the number of newborns exposed to drugs at the time of delivery. But measures of exposure do not necessarily indicate the number of exposed persons with detrimental effects. The toxicity and risk assessment literatures stress the importance of maintaining a distinction, both theoretically and empirically, between the number of persons exposed and the number of persons who have received a biologically effective dose.[14–18] Therefore, a comparison between the data on drug-using parturient women and the data on drug-affected newborns may shed some light on the relationship between exposure to drugs (in the aggregate) at birth and aggregate adverse health outcomes associated with that exposure.

The basis for such a comparison was published in the paper on newborns discussed above.[3] In that paper we examined the historical trend between 1979 and 1987 in the number of newborns discharged with a drug diagnosis. All newborns with one or more drug diagnoses on their discharge records were labeled as "drug-affected." While the phrase "drug-affected newborn" does not imply any adverse health condition other than the existence of a drug diagnosis on the discharge record, many newborns with a drug diagnosis had adverse health problems at birth. For example, about 84% of all newborns with a drug diagnosis had either drug withdrawal symptoms (ICD-9-CM code 779.5) or a nondrug medical diagnosis indicating health problems other than drug exposure. The remaining 16% were coded 760.72, indicating the presence of narcotics without any specified adverse health outcome.

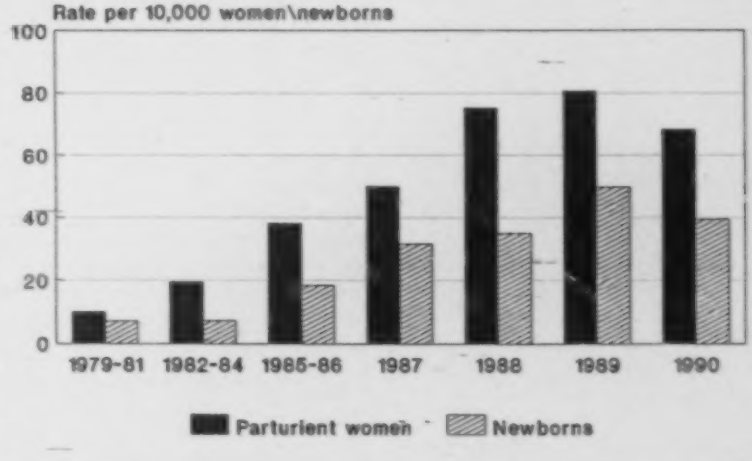

FIGURE 1—Average annual rates of women and newborns with drug-related diagnoses: United States, 1979 through 1990.

Combining data on drug-affected newborns from the previous paper with new data for the 1988 through 1990 time period calculated for this paper, Figure 1 compares the historical trend between 1979 and 1990 in the discharge rate for drug-using parturient women and drug-affected newborns (as defined above). The overall curve for drug-using parturient women is very similar to the overall curve found for drug-affected newborns. Both show a rapid and continuous rise in the rate of drug-related discharges until 1989 and then a decrease in 1990. The overall similarity in the shape of the historical trend for the two populations suggests two things: first, that these two populations represent two aspects of one phenomenon, drug exposure among newborns, and second, that each of the

TABLE 3—Estimated Average Annual Number and Rate of Discharges with a Drug Diagnosis for Newborns and Parturient Women, for the Combined 3-Year Period 1988 through 1990

Population	Average Annual No. of Discharges: Total	Average Annual No. of Discharges: With a Drug Diagnosis	SE for Drug Discharges	Estimated Range of the No. of Discharges with a Drug Diagnosis: Low	Estimated Range of the No. of Discharges with a Drug Diagnosis: High	Rate per 10 000
Newborns	3 828 702	15 846	2 519	10 908	20 784	41.4
Parturient women	3 914 271	29 196	3 334	22 660	35 731	74.6

Note. Years were combined to get a best estimate. Sample size for parturient women with a drug diagnosis for the combined years is 799. Sample size for drug-affected newborns for the combined years is 512. A discharge was counted as a drug-diagnosis discharge if any of up to seven diagnoses on the discharge record was a drug diagnosis. Standard errors were estimated from empirical equations in the documentation accompanying public use tapes for these years. The "low" and "high" estimates are based on 95% confidence intervals.

Source. National Hospital Discharge Survey, NCHS (original tabulations from public use tapes).

populations is a reliable indicator of the national historical trend in drug-related discharges associated with pregnancy in short-stay hospitals in the United States. The decrease in the rate for 1990 is suggestive because it is found in both populations examined. Whether this 1-year decline in the otherwise continuous increase represents the beginning of a long-term decrease or is merely a short-term phenomenon cannot be ascertained at this time.

Although the curves are similar, the rates shown in Figure 1 also suggest that the two populations do not represent exactly the same phenomenon. In every time period examined, the rate per 10 000 for drug-using parturient women was notably higher than the rate per 10 000 for drug-affected newborns. Of the seven possible comparisons in Figure 1, five differences are statistically significant at the .05 level, and these differences are important in an absolute sense. On the average, over all 12 years, the number of drug-affected newborns was only 53% of the number of parturient women diagnosed as using drugs.

Best estimates for 1988 through 1990. For comparisons with other studies in the literature, average estimates for the 3 years 1988 through 1990 are desirable because the single estimates in this paper for these years are not statistically different from one another ($P > .05$). Furthermore, the direction of the historical trend is inconsistent, first rising and then falling over this time period. This seems to indicate a leveling of the historical trend, which is best represented by a single average estimate. Such an estimate is also based on a larger number of sample cases, thus increasing statistical reliability.

Table 3 indicates that the average annual estimate of the number of discharges for drug-using parturient women in the United States during 1988 through 1990 was 29 196 discharges per year (95% CI = 22 668, 35 731). For drug-affected newborns, the average annual estimate for the same 3 years was 15 846 discharges per year (95% CI = 10 908, 20 784). The associated average annual rate of drug use per 10 000 parturient women was 74.6; the average annual rate of newborns who were born drug-affected was 41.4 per 10 000.

Discussion

The Historical Trend

The results reported here give strong support to the perception that an epidemic of drug use among pregnant women occurred in the United States between 1979 and 1990,[19] although changes in physicians' reporting practices and increased use of improved drug testing technology may have also contributed to the results.[3]

A reverse trend for drug use has been reported among women of childbearing age (i.e., between the ages of 15 and 45).[1] Khalsa and Gfroerer, using the Household Survey on Drug Abuse sponsored by the National Institute on Drug Abuse, show that the rate of previous-month drug use among these women decreased from about 1500 drug-using women per 10 000 in 1985 to about 800 in 1990.[1] This is a 47% drop in the rate for previous-month users over this 5-year period.

These contrasting results suggest that modeling drug use among pregnant women on the basis of drug use among women of childbearing age, as was done in a recent Institute of Medicine study,[20] would lead to erroneous estimates of both direction in historical trend and incidence of use. Drug-using parturient women seem to be a distinct subpopulation within the larger population of childbearing women, who have historically been immune to the social forces causing drug use to decrease. Instead, countervailing forces increased drug use among this subpopulation.

Assessing Incidence

Each annual discharge in the NHDS represents both a new case (incidence) and a specific person because it is rare for a woman to deliver more than one child in a 12-month period. Given that this assumption is valid, neither the data for parturient women nor the data for newborns support the higher national estimates of the number of drug-using pregnant women (or drug-exposed newborns) presented in the literature for the years 1988 through 1990. Most of these estimates have ranged between 100 000 and 739 000 women or newborns with a drug diagnosis.[20–26] The best annual estimate for these years based on the NHDS is only 29 196 drug-using women or newborns exposed to drugs. The best annual estimate of the number of drug-affected newborns is 15 846. These numbers raise questions about the reliability and validity of the higher national estimates found in the literature. Because none of the other estimates were derived from surveys with both representative samples of all births in the United States and reliable data collection techniques, these findings suggest that the number of drug-using pregnant women and drug-affected newborns was much smaller in this time period than previously thought.

Adjusting for Underreporting

One criticism of using the NHDS to study the incidence of drug-related discharges is that the survey produces low numbers because drug use is underreported on discharges. We used findings on underreporting from local drug testing studies comparing self-reports with biomarker indications (urine, hair, meconium, and so forth) to construct an algorithm for adjusting estimates from the

NHDS.[3] While these studies varied greatly in the amount of false reporting found, an upper bound for underreporting could be assessed. The results suggested that findings from the NHDS should be weighted by a multiplier of 3 for estimates from 1986 through 1990.[3] This statistical adjustment for underreporting is found in Table 4.

Because the adjusted numbers in Table 4 represent statistical adjustments based on a limited number of studies from local hospitals in areas of high drug use, they should be thought of as provisional, but they are nevertheless revealing. They indicate that after adjustment for probable underreporting, only about 88 000 pregnant women per year can be estimated to have used illicit drugs at the time of delivery in the United States during the 1988 through 1990 time period (95% CI = 67 984, 107 192). During the same time period, after adjustment for underreporting, the estimate is that only about 48 000 newborns might have been adversely affected by drugs annually in the United States (95% CI = 32 726, 62 350). The equivalent estimated national rates per 10 000 are 224 drug-using parturient women and 124 drug-affected newborns.

TABLE 4—Estimated Average Annual Number and Rate of Discharges with a Drug Diagnosis for Newborns and Parturient Women, Adjusted for Underreporting, for the Combined 3-Year Period 1988 through 1990

Population	Average Annual No. with a Drug Diagnosis	Adjustment Factor	Adjusted No. with a Drug Diagnosis	Adjusted SE	Adjusted Range of the No. with a Drug Diagnosis		Adjusted Rate per 10 000
					Low	High	
Newborns	15 846	3	47 538	7 557	32 726	62 350	124.2
Parturient women	29 196	3	87 588	10 002	67 984	107 192	223.8

Assessing Risks to the Newborn

Perhaps the most interesting finding of this study is the gap in incidence between the number of drug-using parturient women and the number of drug-affected newborns. This gap was found in each time period and was always in the same direction. While the gap varied in size among time periods, on average over all 12 years the number of discharges for drug-affected newborns was estimated to be only about half (53%) of the number of discharges for drug-using parturient women.

Two possible explanations (or hypotheses) for this phenomenon come to mind, neither of which can be tested with the data on hand. The first, and most likely, explanation is that the gap represents an exposure–toxicity relationship. In the exposure–toxicity hypothesis, the gap represents the aggregate risk that a drug-exposed newborn will have an adverse health outcome. There is support for this explanation in the literature. For example, the biomarker literature suggests that many exposed newborns appear normal at birth despite a finding of drug use by the mother.[27] Also, Chasnoff reports that fewer than half of newborns exposed to cocaine in utero show any adverse effects at the time of birth.[22] This explanation of the gap is also consistent with the general model for environmental risk assessment research recommended by the Environmental Protection Agency.[15,16]

The second explanation is that the gap represents reporting errors. For the reporting error hypothesis to be likely, the recording of diagnoses for parturient women and newborns would have to represent independent acts wherein knowledge of the medical condition of one partner in the mother–newborn pair does not affect the diagnosis given the other partner. This condition does not hold for the diagnoses under investigation here. For example, it is hard to believe that attending medical personnel who are aware that the mother used drugs prior to delivery would not diagnose the newborn as drug-affected unless the newborn appeared unaffected by the mother's use of drugs. This implies the hypothesis that, during the 1980s, it was customary for medical personnel to give a known drug-exposed newborn a drug diagnosis only when the newborn either had a diagnosable adverse medical condition or tested positive for drugs. From a risk assessment perspective, therefore, a parturient woman could be correctly diagnosed as drug-using while her newborn was not diagnosed as drug-affected, implying an exposure–toxicity relationship of less than one.

Errors in the opposite direction also do not invalidate the exposure–toxicity hypothesis. These errors occur when a physician discovers that a newborn has tested positive for drugs but fails to classify the mother as drug-using. Such errors underestimate the number of drug-using parturient women, making the incidence gap smaller than it otherwise would be.

The consistency, size, and direction of the gap, plus the lack of independence in diagnoses, make it unlikely that the gap is primarily the result of reporting errors. Rather, the gap represents the risk, when examining aggregates, of an adverse health outcome among newborns exposed to drugs near the time of delivery.

While this risk (approximately 0.5) suggests a very high rate of toxicity if all cases are attributed to drug exposure, it raises questions about some methods used in the literature to estimate the number of drug-affected newborns at birth. For example, studies that use the number of drug-using pregnant women as a surrogate measure of the number of newborns adversely affected by drugs would overstate this number by about 100%. The key variable in assessing the burden on hospital services of exposure to a toxic substance is not the number exposed but the number adversely affected by the exposure. If there is no adverse health outcome, then there is no medical reason for special treatment, longer lengths of stay, or other extra services that lead to higher costs and additional burdens on a hospital system. Studies that use an estimated national incidence of more than 50 000 adversely affected newborns to estimate the national hospital costs associated with drug-related births (such as that of Phibbs et al.[28]) overstate the burden on the US hospital system.

Furthermore, the results presented here on the number of drug-affected newborns only indicate an upper bound for the possible toxic effect of drug use (in the aggregate) during pregnancy. This is because evidence is accumulating that many pathological conditions in the newborn thought to be directly attributable to drugs may instead be attributable to other causes associated with drug use by the mother.[2,14,29–32]

Our findings support the perception that drug use among pregnant women steadily increased during the 1980s until 1988, when it appeared to level off. However, the findings do not support

other perceptions concerning drug use during pregnancy. The estimated number of drug-using pregnant women and drug-affected newborns in the 1988 through 1990 time period was much smaller than would be expected on the basis of other reports in the research literature and popular media. The reason for the discrepancy seems to be a lack of representative samples and reliable data collection methods in the studies from which these reports were derived. Finally, the risk of an adverse health outcome among newborns exposed to drugs was found to be much smaller than the risk implied in many discussions of drug use during pregnancy. Above all, our findings do not support the model that one instance of drug exposure in the mother always yields an adverse health outcome in the newborn. One must conclude, therefore, that while an epidemic of drug use among pregnant women did take place during the 1980s, both the size and the severity of the epidemic have been overstated. □

Black–White Differences in Serum Cotinine Levels among Pregnant Women and Subsequent Effects on Infant Birthweight

ABSTRACT

Objectives. Higher levels of serum cotinine (a metabolite of nicotine) have been found in Black smokers than in White smokers even after self-reported cigarette dose was controlled. It is unknown whether higher cotinine levels in Black pregnant smokers may increase the risk of delivering an infant of reduced birthweight.

Methods. We analyzed serum cotinine levels of 374 Black and 829 White women who smoked during pregnancy and who delivered between April 1964 and April 1967. Racial differences in the relationship between cotinine and birthweight were examined.

Results. Cotinine levels were 27.4 ng/mL higher in Black smokers after cigarette dose and confounding variables were controlled. Blacks had higher cotinine levels than Whites at each dose. No significant racial differences in the rate of decrease in birthweight per nanogram of cotinine per milliliter were found.

Conclusions. Our results confirm previous research showing higher cotinine levels at each smoking dose in Black smokers than in White smokers. Because there was no difference in the rate of decrease in birthweight due to cotinine, our results suggest that cigarette smoking among Blacks may have a greater effect on birthweight than it does among Whites. Introduction

Black infants in the United States suffer from rates of low birthweight that are twice as high as those of White infants.[1] Although maternal smoking has been singled out as one of the most preventable risk factors for low birthweight,[2] little research has been conducted to examine whether Blacks are more susceptible to the reproductive hazards of cigarette smoke than Whites.[3,4]

Biochemical validation of smoking behavior in pregnant women by the measurement of cotinine, a major metabolite of nicotine, has been found to be a better predictor of birthweight than self-reported number of cigarettes per day.[5] In addition, serum cotinine levels in nonpregnant Black smokers have been found to be higher than those in White smokers even after controlling for a number of behavioral and personal characteristics, including self-reported cigarette dose.[6] Wagenknecht et al.[6] suggested that these higher cotinine levels in Blacks may reflect differences in nicotine absorption or metabolism. Others have suggested that these high cotinine levels may be due to racial differences in smoking characteristics or life-style.[7] It is unknown whether these racial differences persist in pregnant smokers and whether higher cotinine levels in Blacks, if observed, may result in an increased risk of delivering an infant of reduced birthweight.

We assessed the differences in serum cotinine levels among a cohort of Black and White pregnant women from the Oakland, Calif, area who, based on self-report, were smokers. The effects of these differences in cotinine levels on the birthweights of their infants were evaluated.

Methods

Participants

This study was based on a subsample of the Child Health and Development Studies, a longitudinal study that followed women and their offspring enrolled at the Kaiser Permanente Hospital facilities, primarily in Oakland, Calif. Pregnant women were enrolled in the study from 1959 to 1966. Child Health and Development Studies enrollees were socioeconomically diverse, with only the extremes—the very impoverished or the very affluent—not being well represented.[8]

Women were questioned about their smoking status during their first Child Health and Development Studies interview, which usually took place in the first trimester at a prenatal care visit. Serum samples were taken from the gravida in each of the three trimesters and at postpartum. A second interview was conducted in the second half of pregnancy to assess whether any differences in health, attitudes, and behavior had occurred. At the first interview (and second interview if data were available), women who reported that they smoked were classified as smokers; women who had never smoked or who had quit before pregnancy were

Education, %				
Did not graduate from high school	18.1	30.7	8.4	21.2
High school graduate	76.1	64.4	61.2	61.4
College graduate	5.6	4.8	30.3	17.4
Unknown	0.1	...	0.1	...

as nonsmokers. One serum sample was chosen for each woman. The sample used was the closest by date to the average time of the second interview because this time was considered the most critical period for effects on fetal growth.[2] (The mean time for the second interview was 185 days after the woman's last menstrual period.)

Smoking consumption was recorded in the interviews in categories of 1–4, 5–9, 10–14, 15–19, 20–29, 30–39, 40–60, and more than 60 cigarettes per day. For some analyses, level of smoking consumption was recategorized as 1–9, 10–19, and 20 or more cigarettes per day from the initial and the second Child Health and Development Studies interviews. Other smoking information (e.g., the number of years the mother smoked, whether she inhaled and/or smoked nonfilter cigarettes) was also obtained from the initial interview. Other first-interview variables included maternal educational achievement (defined as did not graduate from high school, high school graduate, and college graduate), parity (defined as the total number of previous live births and stillbirths), age, prepregnant weight, height, and race. Body mass index was categorized into four levels: low (<19.8 kg/m^2), medium (19.8–26.0 kg/m^2), heavy (26.1–29.0 kg/m^2), and obese (>29.0 kg/m^2). Data from the second interview were used for the category of number of cigarettes smoked, if this information was available; otherwise, it was taken from the initial interview. Information on birthweight (in ounces) of the infant was obtained from the infant's Kaiser medical chart; gestational age was estimated from last menstrual period as reported in the interview.

Our original sample consisted of 4240 pregnancies (live births and fetal deaths) of Black and White women who were interviewed during pregnancy and delivered between April 1964 and April 1967. We excluded plural births (n = 64), pregnancies with unknown smoking status of the mother (n = 20), and pregnancies with unavailable sera for testing (n = 27). We further excluded those with unknown birthweight or gestational age (n = 142) and those where the mother either started or stopped smoking during pregnancy (n = 397). An additional 247 pregnancies were dropped to limit the sample to one pregnancy per woman; the sibling retained was chosen randomly. The final sample available for analysis was 3343 women, with 374 smokers and 696 nonsmokers among Blacks and 829 smokers and 1444 nonsmokers among Whites. Of these 3343, 68.8% had completed a second interview.

Cotinine Analysis

Once nicotine is absorbed into human tissue via smoking, it is converted to cotinine and other metabolites in a series of steps of oxidative metabolism.[9] Nicotine acts as a vasoconstrictor in both the mother and fetus and is thought to be one of the main compounds in tobacco smoke to induce intrauterine growth retardation.[9] About 70% of nicotine is converted to cotinine, which can be detected in serum.[10] Cotinine has a half-life of 15–20 hours in adults.[11] Frozen 3-cc samples of serum were stored either at a cold storage facility in Oakland, Calif (22.4% of all samples) or in Frederick, Md (77.6% of all samples). The samples were shipped from both facilities to the Clinical Biochemical Laboratories at the American Health Foundation in Valhalla, NY, for analysis. The samples used were collected between 1964 and 1967.

Cotinine was determined by the radioimmunoassay method of Haley et al.[12] after a modification of a technique by Langone et al.[13] The interassay coefficient of variation for cotinine was found to be 10.9%, with a minimal detection limit of 2 ng/mL. Out of the entire population of samples, 10% were blindly selected for duplicate analysis. Cross-tabulation of the duplicate samples of smokers and nonsmokers over five categories[6] of cotinine levels (0–13, 14–99, 100–249, 250–499, and ≥500 ng/mL) yielded an agreement rate of 97%.

Data Analysis

Comparison of median cotinine values by race was done by using the Wilcoxon rank sum test, and confidence intervals (CIs) for the medians were computed based on the binomial method.[14] Spearman correlation coefficients were calculated between the ranked categories of self-reported cigarettes (using the eight-category classification) and serum cotinine. Mantel-Haenszel chi-square values were calculated for categorical data, and comparison of means was done by using *t* tests. Gestational age later than 40 weeks was classified as 40 weeks for analysis.[15]

Simple linear regression models were used for each race and at each dose level to examine the effect of cotinine on birthweight. Because models using the log transformation of cotinine and categorizing cotinine in 100-ng/mL intervals did not explain as much of the variance in birthweight as untransformed cotinine, untransformed cotinine was used in the analysis. Multivariate linear regression models were first run separately for each race for all smokers and at each dose level. Additional multivariate models were run to test for interaction by fitting models with a cross-product term for race and cotinine ($P < .10$). SAS and Confidence

Interval Analysis software was used in the analyses.[16,17]

Results

Table 1 shows the characteristics of women in the study sample stratified by race. Average age was similar for White and Black women ($t = -1.33$, $P = .18$), whereas more White women than Black women were college graduates ($\chi^2 = 210.0$, $P < .001$) and primiparae ($\chi^2 = 160.9$, $P < .001$). More Blacks than Whites had a heavy or obese body mass index ($\chi^2 = 143.7$, $P < .001$). Among both races, more smokers than nonsmokers did not graduate from high school ($\chi^2 = 22.2$, $P < .001$ for Blacks; $\chi^2 = 101.1$, $P < .001$ for Whites).

Analysis of smoking behavior (Table 2) showed that Blacks were more likely than Whites to report smoking fewer cigarettes per day. Blacks were also less likely to inhale and to use nonfilter cigarettes. The number of years smoked and the percentage of women who had husbands who smoked were similar in both races.

Cotinine Levels

Out of all participants who classified themselves as smokers at the interviews (n = 1203), 93.3% (n = 1123) had serum cotinine levels greater than or equal to 14 ng/mL (cutoff level for active smoking[18]). Out of all participants who reported that they were nonsmokers at the interviews (n = 2140), only 2.0% (n = 42) had cotinine levels greater than or equal to 14 ng/mL (false-negative rate). False-negative and positive predictive value rates were 2.9% and 95.5% for Blacks and 1.5% and 92.4% for Whites.

Because we were concerned about sample desiccation given the age of the samples, we examined sodium levels in a random sample of 50 serums from each facility. Average sodium levels were slightly higher than normal (normal range = 137–145 mmol/L) in samples from the Frederick facility (mean = 153.72 mmol/L, SD = 21.59) and even higher in samples from the Oakland facility (mean = 189.38 mmol/L, SD = 36.46). To test the impact of including Oakland samples in this study, we computed the difference in average cotinine levels among smokers, including and excluding samples from the Oakland facility, for each racial group. When excluding these samples, average cotinine levels were only 3% (136.5–132.4 ng/mL) and 1.7% (147.6–145.1 ng/mL) lower in White and Black smokers, respectively (proportions of Whites and Blacks were similar in each facility). These results indicate that there is little evidence of systematic bias of sample desiccation on our analysis by race.

Cotinine levels agreed well with self-reported smoking status in that the median cotinine levels increased with the reported category of the number of cigarettes for Blacks and for Whites (Table 2). The Spearman correlation coefficients for ranked categories of cigarettes and cotinine were 0.52 ($P = .0001$) for Whites and 0.37 ($P = .001$) for Blacks. Previous studies have found correlations between self-reported cigarettes and cotinine of 0.58 (both races),[19] 0.64 in Whites and 0.46 in Blacks.[6]

Although Black smokers reported smoking fewer cigarettes per day, they had higher mean ($P = .05$) and median ($P = .13$) serum cotinine levels than White smokers (Table 2). Black smokers also had higher cotinine levels in each category of self-reported cigarettes smoked per day. We also found that 18.4% of Black smokers compared with 3.9% of White smokers exceeded levels of 25 ng of cotinine/mL per cigarette (cotinine levels per cigarette were derived by using the midpoint of each category of cigarette consumption).[20]

After number of years smoked, number of cigarettes smoked, whether or not the participants used nonfiltered cigarettes, education, and age were controlled for in a multivariate regression model, cotinine levels were 27.4 ng/mL higher in Blacks than in Whites. Cotinine levels stayed significantly higher in Blacks after

TABLE 4—Results of Multivariate Linear Regression[a] of the Effect of Maternal Serum Cotinine on Infant Birthweight, by Race, Child Health and Development Studies, Oakland, Calif, 1964 through 1967

	Mean Difference in Birthweight (g) per ng of Cotinine/mL (95% CI)		
	Black (n = 364)	White (n = 806)	P[b]
All smokers	−1.18 (−1.69, −0.67)	−0.85 (−1.21, −0.50)	.10
Cigarettes/d			
1–9	−1.50 (−2.49, −0.52)	−1.22 (−2.34, −0.11)	.80
10–19	−1.08 (−2.01, −0.15)	−1.73 (−2.55, −0.91)	.38
≥20	−0.82 (−1.79, 0.15)	−0.41 (−0.92, 0.10)	.12

[a]Variables controlled for were education (did not graduate from high school, high school graduate vs college graduate [reference]), maternal age, parity (primiparous, high multiparous vs low multiparous [reference]), gestational age, inhalation, filter cigarette use, number of years smoked, and body mass index (medium, heavy, obese vs low [reference]). Ten records for Blacks and 23 records for Whites were deleted because of missing values.
[b]P value for cross-product term for interaction between race and serum cotinine.

conducting this analysis separately by educational level (not shown).

Relationship of Cotinine to Birthweight

Black women delivered infants weighing on the average 202 g less than infants delivered by White women. Table 3 shows the effect in both races of self-reported smoking on birthweight. Black women smoking 20 or more cigarettes per day delivered infants that weighed on average 277 g (95% CI = 154, 400) less than those delivered by nonsmokers; among Whites, the deficit was 207 g (95% CI = 147, 268).

Among all smokers, the results of simple linear regression (not shown) revealed that cotinine levels were associated with a decrease of 1.13 g per ng of cotinine/mL (95% CI = −1.47, −0.79). Serum cotinine was somewhat more related to birthweight among Blacks than among Whites (−1.22 g per ng/mL [95% CI = −1.86, −0.58] vs −0.98 g per ng/mL [95% CI = −1.37, −0.60]). After stratification by self-reported cigarettes per day, the effect of cotinine on birthweight was found to be larger in White light (1–9 cigarettes/day) smokers than in Black light smokers (−2.30 g per ng/mL vs −1.44 g per ng/mL). However, Black heavy (≥20 cigarettes/day) smokers showed a larger effect of cotinine on birthweight than White heavy smokers (−1.38 g per ng/mL vs −0.48 g per ng/mL).

To examine these racial differences further, we assessed the effect of the amount of cotinine on birthweight while controlling for parity, education, maternal age, body mass index, and smoking behavior variables such as inhalation, nonfilter cigarette use, and the number of years smoked. Table 4 shows the relationship between infant birthweight and serum cotinine derived from multivariate linear regression models run for each race. Among all smoking dose levels, an increase of 1 ng of cotinine/mL resulted in a decrease of 0.85 g (95% CI = −1.21, −0.50) among Whites and a decrease of 1.18 g (95% CI = −1.69, −0.67) among Blacks (*P* value for interaction between race and cotinine = .10). After conducting separate interaction models by self-reported cigarettes per day, no evidence for an interaction (at $P < .10$) between race and cotinine level was found (Table 4).

Discussion

In a study of young Black and White smokers, Wagenknecht et al. found that Blacks had cotinine levels that were 83.3 ng/mL higher than those of Whites after controlling for several characteristics, including number of cigarettes, inhalation frequency, age, and education.[6] After controlling for similar factors in our study of pregnant women, we found that Black smokers had cotinine levels that were 27.4 ng/mL higher than those of White smokers. Like Wagenknecht et al., we also found that Black smokers had higher serum cotinine levels at each level of self-reported cigarette consumption.

Although not statistically significant in this study, the effect on birthweight of self-reported smoking appeared to be greater in Blacks than in Whites. Blacks smoking a pack or more of cigarettes a day delivered infants that weighed on average 277 g less than those delivered by nonsmokers. The birthweight decrement in Whites smoking a similar amount was only 207 g.

After analyzing the relationship between serum cotinine and birthweight, we found little evidence for a racial difference in the *rate* of reduction in birthweight per ng of cotinine/mL, even after controlling for maternal factors and smoking behavior including self-reported cigarette consumption (Table 4). However, Blacks had higher levels of cotinine at each category of cigarette dose (Table 2). Thus, these data suggest that the per-cigarette effect on birthweight may be greater in Blacks than in Whites.

The higher average cotinine levels among Blacks may be due to several factors. First, it has been previously suggested that the higher levels may be due to differences in nicotine metabolism.[6] The amount of cotinine measured in serum is dependent not only on the original dose of nicotine absorbed and the rate of conversion of nicotine to cotinine, but also on the rate of excretion.[10] Factors such as exercise and physical fitness may also affect nicotine metabolism.[7] Although we were able to control for body mass index as a measure of fitness, we were unable to assess whether racial differences in exercise or cotinine excretion rates exist in this study.

Second, a possible explanation for this racial difference could be differential self-report. In a controlled study,[21] heavy smokers that were restricted to only a few cigarettes (and therefore expected to have a higher intake of smoke per cigarette) did not exceed 25 ng of cotinine/mL per cigarette. It has been suggested, therefore, that smokers that exceed this level may have underreported their cigarette consumption.[20] We found that 4.7 times as many Black smokers as White smokers exceeded levels of 25 ng of cotinine/mL per cigarette. In addition, we found that the false-negative rate (percentage of nonsmokers with cotinine levels of ≥14 ng/mL) in Blacks was almost double the rate of Whites (2.9% vs 1.5%, respectively).

In contrast, we found that Black smokers continued to have higher cotinine levels than White smokers after stratifying by educational group. Any underreporting would be expected to vary by educational level.[6] Further, no evidence of a systematic racial bias in self-report of cigarette consumption has

been reported in the National Health Interview Survey,[22] and Wagenknecht et al. have estimated that Black smokers in their study would have to smoke twice as much as reported to explain the race differential in cotinine levels.[6]

Finally, differences in cotinine levels may also be due to racial variations in smoking characteristics. In this study, more Whites than Blacks were heavy smokers, inhaled, and smoked nonfiltered cigarettes. Therefore, we would have expected that White smokers would have greater exposure to nicotine than Black smokers and hence higher, not lower, cotinine levels. However, we lacked information on smoking behavior such as brand preference, mentholated cigarette consumption, and length of cigarette smoked, which may affect nicotine exposure.[7] It has been reported that Black smokers actually smoke less of their cigarettes than White smokers.[23] Further, Black smokers have been previously found to have higher serum cotinine levels than White smokers even after controlling for mentholation of the cigarette.[6]

In conclusion, Black pregnant smokers in this study were found to have higher serum cotinine levels than White smokers after controlling for smoking dose and demographic confounders. Given these higher levels and the fact that we found no racial difference in the rate of decrease in birthweight per nanogram of cotinine per milliliter, these data suggest that cigarette smoking among Blacks may have a greater effect on birthweight than it does among Whites. Experimental studies are needed to better characterize racial differences in nicotine exposure and cotinine levels. □

Acknowledgments

This study was supported by funds provided by the Cigarette and Tobacco Surtax Fund of the state of California through the Tobacco-Related Disease Research Program of the University of California (grant number 1RT465).

We thank the Child Health and Development Studies for the use of their data. Drs Neil Benowitz, Robert Engel, Jeffrey Gould, Nancy Haley, Martin Kharrazi, William Satariano, and Lynne Wagenknecht made helpful suggestions on an earlier draft. Caryn Axelrad of the Clinical Biochemistry Facility of the American Health Foundation conducted the cotinine analysis.

Birthweight Differentials among Asian Americans

Gopal K. Singh, PhD, MS, and Stella M. Yu, ScD, MPH

ABSTRACT

Objectives. This study examines differentials in mean birthweight and the risk for low birthweight among various Asian-American groups in New York State (n = 499 377).

Methods. Using resident singleton live-birth records from New York State for 1985 and 1986, Asian-American births were compared with Black, American Indian, and White births. Multivariate ordinary least squares and logistic regression models were used to analyze ethnic differences.

Results. Compared with White births, the expected mean difference in birthweight was −115 g for Chinese, −235 g for Japanese, −164 g for Filipinos, −120 g for Blacks, and 74 g for American Indians. The risk for low birthweight was 45% higher for Filipinos and 49% higher for Blacks as compared with Whites.

Conclusions. Results of this study suggest substantial heterogeneity in mean birthweight and risk for low birthweight among ethnic groups in general and the major Asian-American groups in particular. Interestingly, after controlling for ethnic differences in sociodemographic risk factors, Filipinos appear to resemble Blacks much more closely than they do their Japanese and Chinese counterparts with respect to risk for low birthweight. (*Am J Public Health.* 1994;84:1444–1449)

Introduction

The significance of birthweight as one of the most important determinants of infant mortality and morbidity is well documented in social and biomedical research.[1] For infants of low birthweight (i.e., less than 2500 g), the risk of dying in the first year of life is about 21 times that for infants weighing 2500 g or more. For infants of very low birthweight (i.e., less than 1500 g), the risk is considerably greater: about 90 times that for infants weighing 2500 g or more.[2] According to the most recent vital statistics data, the rate of low birthweight (percentage of newborn babies weighing less than 2500 g) in the United States was 7.1% in 1991. However, this rate varied substantially among the various racial and ethnic groups. For White infants it was 5.8%, for Black infants it was 13.6%; and for American Indians and Asian-American groups such as Japanese, Filipinos, and Hawaiians, it was 6.2%, 5.9%, 7.3%, and 6.7%, respectively, all somewhat higher than that observed for White infants. The rate was lowest for Chinese infants (5.1%).[3]

Given these statistics and the particularly strong impact of birthweight on infant mortality and morbidity, it is not surprising that numerous studies have attempted to analyze risk factors associated with low birthweight. However, there is a paucity of studies that have examined racial/ethnic differentials in birthweight among US populations other than Whites, Blacks, and Hispanics.[4] Especially lacking are birth outcome studies on specific Asian-American subgroups, some of which are among the fastest growing minority groups in the United States.[5,6]

Despite the presence of marked heterogeneity among Asian Americans, studies investigating ethnic differentials in socioeconomic characteristics and birth outcomes have often treated Asian Americans as a single entity.[7–9] However, previous research using linked birth and infant death records has demonstrated important variations among Asian Americans in infant mortality rates by age at death[10–15] and cause of death.[16] Similarly, profound differences among these people have been noted with respect to low birthweight and associated risk factors.[4,11] Results of this paper further illustrate the substantial heterogeneity that exists within the Asian-American population with respect to sociodemographic characteristics and birth outcomes.

The purpose of this study is to examine ethnic differentials in mean birthweight and risk for low birthweight, with special emphasis on three major Asian-American groups: Chinese, Japanese, and Filipino Americans. We evaluate birth outcomes among these three groups relative to those for White, Black, and American Indian infants. The specific questions we investigate are (1) whether these racial/ethnic groups differ significantly with respect to mean birthweight and risk of low birthweight, and (2) whether these differentials, if they exist, persist after controlling for selected sociodemographic and biological risk factors.

Data and Methods

Data

The data used in this study are derived from the National Linked Birth/Infant Death Data Sets for 1985 and 1986 birth cohorts.[2,17] From these two national files were extracted all the resident singleton live births that occurred in New York State during those 2 years.

For the purpose of this analysis, White, Black, American Indian, Chinese, Japanese, and Filipino live births in New York State in 1985 and 1986 were considered. The births occurring to other ethnic groups, including other Asian Americans, were excluded because of insufficient numbers of live births for analysis. The study sample for New York State thus consisted of 499 397 singleton live births, with Chinese, Japanese, and Filipino births in the sample accounting for about 1.5% of all births in the state. It is important to note that all live births were classified according to maternal race/ethnicity.

The rationale for selecting New York State was threefold. First, it is impractical and costly to conduct a multivariate analysis at the national level using all 3.7 to 4.1 million births that occur during a specific calendar year in the United States. Second, although a large proportion (about 40%) of Asian-American births occur in California, that state could not be included in the analysis because information on maternal education—an important covariate of birth outcome and the only measure of socioeconomic status available from vital statistics data—is not recorded on its birth certificates. Third, the population of New York State is ethnically quite diverse, yielding sufficiently large numbers of live births for each of the ethnic groups considered here.

Variables

The dependent variables in this study were mean birthweight and risk of low birthweight. In estimating the risk of low birthweight, all the live births weighing less than 2500 g were defined to be of low birthweight.[18] Differences in these two dependent variables were modeled as functions of both sociodemographic and biological risk factors. More specifically, the risk factors (covariates) considered to influence birthweight included maternal background factors (e.g., age, race/ethnicity, educational attainment, nativity, marital status, county of residence, and prenatal care) and infant characteristics (e.g., birth order, sex, and gestational age).[19] Maternal education and prenatal care were measured as continuous variables, while all other covariates, including race/ethnicity, were measured as categorical variables.

Methods

Ordinary least squares regression was used to analyze ethnic differences in mean birthweight while multiple logistic regression was used to analyze ethnic differences in the risk of low birthweight, controlling for the effects of other covariates. The parameters in the ordinary least squares model, which represented the effects of covariates including ethnicity, were estimated using the REG procedure; those in the logistic model were estimated by the maximum likelihood method using the LOGISTIC procedure of SAS, Version 6.[20]

Racial/ethnic differentials in mean birthweight and risk of low birthweight were examined by fitting a series of hierarchical regression models, keeping in mind the causal sequencing of the risk factors in their associations with birthweight. In the first stage, regression models were fitted to determine crude (unadjusted) differentials in mean birth-

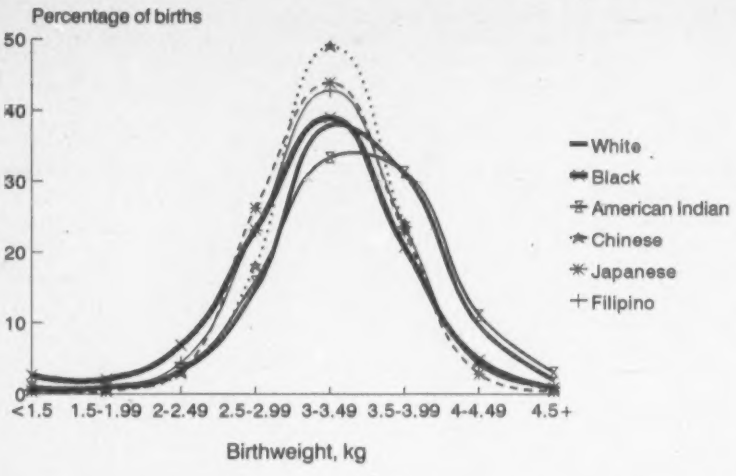

FIGURE 1—Birthweight distribution by maternal race/ethnicity: New York State, 1985 to 1986.

weight and risk of low birthweight between Whites and each of the other ethnic groups. In the second stage, ethnic differentials were investigated by entering race/ethnicity, maternal age, education, marital status, nativity, place of residence, birth order, infant sex, and prenatal care into the model. The final model examined ethnic differentials, incorporating all the covariates including gestational age.

Results

Table 1 shows descriptive data on birth outcomes and selected maternal and infant characteristics by race/ethnicity. As seen in this table, Chinese, Japanese, and Filipino infants weighed significantly less at birth (about 120 to 180 g less) than White infants. Black infants had the lowest mean birthweight, approximately 250 g less than their White counterparts. American Indians had on average about the same birthweight as Whites. However, Chinese, Japanese, and Filipino Americans had a much more compact birthweight distribution, showing substantial clustering around the mean birthweight, whereas White, Black, and American Indian babies showed considerable dispersion below and above the mean (see Figure 1). This also implies that variation in birthweight among Asian Americans was substantially lower than that among Whites, Blacks, and American Indians, which is also evident by looking at the differences in standard deviations of race/ethnic-specific birthweight shown in Table 1.

According to the figures in Table 1, Chinese had the lowest rate of low birthweight, about 22% lower than the White rate and 32% lower than the Filipino rate. Rates of low birthweight for Japanese, Filipinos, and American Indians were not significantly different from that for Whites. However, Blacks had the highest rate—about 2.3 times that for Whites and nearly three times that for Chinese.

The groups with the highest rates of low birthweight appear to have the least favorable distributions on several of the risk factors (see Table 1). For example, the percentage of births to mothers aged 19 or less, the incidence of nonmarital childbearing (as measured by the proportion of births occurring to unmarried mothers), and the proportion of fourth- and higher-order pregnancies were substantially higher among Blacks, American Indians, and Whites than among Asian groups. Similarly, the proportion of preterm births was higher among Blacks, American Indians, and Whites than among Chinese, Japanese, and Filipinos. Additionally, not only did Black and American Indian mothers have, on average, fewer years of schooling than their Asian counterparts, but they were also significantly less likely to have attained a college education, and a somewhat lower proportion of them sought prenatal care during the first trimester of pregnancy.

Ethnic Differentials in Mean Birthweight

Results of multiple linear regressions examining the effects of race/ethnicity and other covariates on mean birthweight are presented in Table 2. When only race/ethnicity was considered, all groups except American Indians differed significantly from Whites in mean birthweight (model 1). When maternal age, education, marital status, nativity, county of residence, birth order, infant sex, and prenatal visits were introduced as controls in model 2, the Black/White differential in mean birthweight decreased by 108 g and the Chinese/White differential decreased by 8 g, while the Japanese/White, Filipino/White, and American Indian/White differentials increased by 67, 24, and 55 g, respectively. In other words, the standardized differences in mean birthweight between Whites and Japanese, Filipinos, and American Indians were larger and those between Whites and Blacks were significantly smaller than the corresponding crude observed differences in model 1.

The other covariates in model 2 were related to birthweight in the manner expected. Maternal age of 35 years and older; first-order, female, and out-of-wedlock births; mother's metropolitan residence, US-born status, and lower educational attainment; and fewer prenatal visits were all associated with significantly lower mean birthweights. Model 3 shows the ethnic differentials in mean birthweight after controlling for the additional effect of gestational age. Relative mean differences in birthweight among ethnic groups changed only slightly, revealing essentially similar patterns as those observed in model 2. Compared with White births, the expected mean difference in birthweight was −115 g for Chinese, −235 g for Japanese, −164 g for Filipinos, −120 g for Blacks, and 74 g for American Indians.

Ethnic Differentials in Risks for Low Birthweight

Since the analysis of ethnic differentials in mean birthweight may be affected by ethnic differences at the lower and upper extremes of the birthweight distribution, a separate analysis of low birthweight is warranted to identify risk factors associated with ethnic differentials in birth outcome. The results of this analysis are presented in Table 3. Clearly, the results of Table 2 are reinforced by the ethnic differentials in the risk for low

birthweight estimated by logistic regression in models 1 through 3 of Table 3. Model 1 in Table 3 presents the crude effect of race/ethnicity on the risk for low birthweight. The category showing an odds ratio of 1.00 represents the reference group used for comparison. Compared with White infants, Black infants had a 148% higher risk for low birthweight whereas Chinese had a 22% lower risk. However, the differences in low-birthweight rates between Whites and Japanese, Filipinos, and American Indians were not statistically significant. Not surprisingly, the results in model 1 of Table 3 are consistent with those reported earlier while discussing the ethnic differentials in low birthweight rates in Table 1.

To further explain ethnic differentials in risks for low birthweight, we added to model 1 sociodemographic risk factors, as mentioned above. Results of this stage are shown in model 2. Controlling for the confounding effects of these covariates reduced ethnic difference in risks for low birthweight for Black infants from 148% to 59% but increased significantly the difference for Filipino infants from 15% to 54%. However, differences in risks for low birthweight between Whites and Japanese, Chinese, and American Indians were not statistically significant.

The remaining results in model 2 of Table 3 are consistent with expectations concerning the relationships of the covariates considered and the risks for low birthweight. Births to unmarried mothers as well as to mothers aged 35 and over, out-of-wedlock births, first- and fourth- or higher-order pregnancies, and births to US-born mothers were all associated with a significantly higher risk for low birthweight. Furthermore, that risk declined significantly with increasing levels of education and prenatal care, even after controlling for the effects of other covariates.

Next added to model 2 was gestational age, the findings of which are shown in model 3 of Table 3. Compared with the other risk factors, gestational age had the strongest net impact on the risk for low birthweight. Although its inclusion in the model somewhat narrowed the ethnic differentials in low birthweight, Filipino and Black infants continued to show significantly higher risks for low birthweight than Whites—45% and 49%, respectively.

Discussion

This study has examined ethnic differentials in birthweight using resident singleton live-birth records from New York State for 1985 and 1986. The two specific questions addressed were (1) whether the Asian-American groups such as Chinese, Japanese, and Filipinos differed from Whites, Blacks, and American Indians with regard to mean birthweight and risk for low birthweight; and (2) whether the ethnic differences remained after controlling for selected sociodemographic and biological risk factors known to influence birth outcome. The analysis initially revealed important ethnic differences, with Chinese, Japanese, and Filipinos showing significantly lower mean birthweights than White infants. Controlling for such sociodemographic factors as maternal age, education, marital status, nativity, birth order, and prenatal care had a narrowing effect on the relative birthweight differ-

ences between Whites and Blacks and Chinese but had a widening impact on the mean birthweight differences between Whites and Japanese, Filipino, and American Indians.

Similarly, observed ethnic differences in rates of low birthweight indicated a significantly lower risk for low birthweight for Chinese and a higher risk for Blacks compared with Whites. Adjustment for the risk factors mentioned above reduced but did not completely eliminate ethnic differences in low birthweight.

Results of this study also point toward the substantial heterogeneity that characterizes the three Asian-American groups with respect to their sociodemographic composition and birth outcome. Of the three groups, Chinese mothers appear to have the most favorable birth outcome although they have lower educational attainment than Japanese and Filipino mothers. Comparison of their standardized low-birthweight rates (after adjusting for risk factors) reveals that Japanese and Filipino mothers were significantly more likely (38% and 56%, respectively) to have a low-birthweight baby than Chinese mothers. In fact, based on ethnic differences in standardized low-birthweight rates, Filipinos appear to resemble Blacks much more closely than they do their Japanese and Chinese counterparts with respect to the risk for low birthweight.

As regards the generalizability of this study, the Asian-American population in New York State may not be entirely representative of the Asian-American population in the United States as a whole. As seen from Table 1, Chinese, Japanese, and Filipino mothers in our sample consist almost entirely of immigrants, with significantly larger proportions of them having been born abroad than is the case at the national level.[11,16] As a result, these mothers differ somewhat from their national counterparts in their sociodemographic composition and therefore in their birth outcomes; for example, Chinese, Japanese, and Filipino mothers in New York State had fewer prenatal visits and were relatively less likely to seek early prenatal care. Furthermore, compared with their national counterparts, Japanese and Filipino mothers in New York State were characterized by higher maternal education and lower rates of teenage, fourth- and higher-order, and out-of-wedlock births.[11,16] Additionally, Chinese mothers in our study sample (which includes New York City) were relatively more likely to be newer immigrants and to be less educated, poor, and employed in secondary labor markets than is the case nationally.

In conclusion, the results of this study indicate important ethnic differences in mean birthweight and risk of low birthweight. But while sociodemographic risk factors considered here account for some of these observed differences, much of the variance in birth outcomes among ethnic groups in general and among Asian Americans in particular remains unexplained. To explain more fully the ethnic differences in mean birthweight and risk of low birthweight will require consideration of additional risk factors not included in the present analysis owing to lack of data. Examples of these risk factors include such socioeconomic variables as income and occupation; behavioral or life-style factors such as maternal cigarette smoking, alcohol consumption,

and other forms of substance abuse; nutritional factors such as maternal and paternal size, gestational weight gain, diet, and breast-feeding; psychosocial[21] and cultural factors such as stress, social and familial support, and cultural attitudes toward maternity; and medical care factors that are more directly related to birth outcomes.[19] Maternal occupation and especially income may contribute substantially to ethnic variations in birth outcomes independent of education, the most commonly used measure of socioeconomic status in the analysis of health outcomes.[22] Maternal physical stature as measured by height and prepregnancy weight is shown to have a profound net effect on birthweight[9,18] and is expected to account for part of the reported birthweight deficit for Asian-American groups considered in this study. However, significant ethnic differentials in both–mean birthweight and risk of low birthweight have been shown to persist even after controlling for ethnic differences in maternal body size and other covariates.[9,23] □

The Relationship of Prenatal Care and Pregnancy Complications to Birthweight in Winnipeg, Canada

Cameron A. Mustard, ScD, and Noralou P. Roos, PhD

ABSTRACT

Objectives. Prenatal care is commonly understood to have a beneficial impact on birthweight. This study describes socioeconomic differences in utilization of prenatal medical care and birthweight in a population with universal health insurance.

Methods. Measures of prenatal care utilization, incidence of pregnancy complications, and birthweight were obtained from physician reimbursement claims and hospital separation abstracts for 12 646 pregnant women. Maternal socioeconomic status was derived from small-area census data.

Results. Infants born to women in the poorest income quintile had lower birthweights than infants born to wealthier women. Much of the difference was associated with a higher prevalence of complications, smoking, unmarried status, and inadequate prenatal care among low-income women. The difference in birthweight between adequate and less than adequate care groups was small, and the benefit associated with prenatal care was no greater among women with pregnancy complications.

Conclusions. The lower utilization of prenatal care by poorer women accounted for a small proportion of the difference in birthweight. Socioeconomic differences in birthweight are primarily attributable to factors not directly influenced by early prenatal medical care. (*Am J Public Health.* 1994;84:1450–1457)

Introduction

Prenatal care is commonly understood to have a beneficial impact on pregnancy outcome, either through the diagnosis and timely treatment of complications or by contributing to the elimination or reduction of modifiable maternal risk factors. Prenatal care may extend the length of gestation,[1,2] and early initiation of care has been associated with heavier birthweights.[3–6] However, the efficacy and effectiveness of prenatal care as a primary or secondary intervention in the prevention of low birthweight is unresolved. The substantial increase in the proportion of US women initiating care in the first trimester in the past 2 decades has not been accompanied by a significant decline in the incidence of low-birthweight infants.[7,8] Although prenatal care contributes to the identification of complications during pregnancy, the early initiation of regular prenatal care has not been shown to directly reduce the incidence of low birthweight[1,4,6,9–16] or to moderate the incidence of preterm birth.[17–19]

Where prenatal care can be shown to be effective, constraints on access to such care limit the numbers of women who may derive benefit. Canada's universal first-dollar insurance for medical care, although necessary to achieve high population coverage of prenatal services, may be insufficient to achieve equitable access.[20–26] We designed a study with two principal objectives: (1) to describe the utilization of prenatal care in relation to maternal socioeconomic characteristics in a universally insured health care system and (2) to assess the effectiveness of prenatal care, specifically the contribution of prenatal care in mitigating the effects of pregnancy complications on birthweight.

Methods

Population and Study Period

The study population consisted of the 13 349 women resident in metropolitan Winnipeg, Manitoba, who had hospital admissions resulting in live births in the 18-month period between July 1, 1987, and December 31, 1988. Excluded from this population were 288 women (2.2%) whose hospital separation abstract could not be linked to a newborn hospital record and 415 women (3.1%) who were not registered with the Manitoba Health Services Insurance Plan for the complete pregnancy interval. After these exclusions, 12 646 women were retained in the study sample.

Sources of Data

Information on prenatal care was gathered from three computerized administrative databases maintained by the Manitoba Health Services Insurance Plan: hospital separation abstracts; physician claims for reimbursement of ambulatory care, including diagnostic tests performed in a physician's office or a laboratory; and records of the provincial postpartum follow-up nursing program. The three sources of administrative data contain common personal identifiers that permit records to be combined to create a

composite maternal history of prenatal care. These data were supplemented by descriptions of neighborhood socioeconomic characteristics derived from the 1986 Canadian census.

Hospital separation abstracts. Individual separation abstracts are issued for mothers and their newborns. The newborn separation abstract contains information on birthweight, Apgar score at 1 and 5 minutes, gestational age, and a range of *International Classification of Diseases,* Ninth Revision, Clinical Modification[27] (ICD-9-CM) diagnostic codes describing neonatal morbidity. The maternal obstetrical record provides information on age; residential postal code; treaty Indian status; parity; gravidity; ICD-9-CM diagnostic codes defining morbidity associated with pregnancy, labor, and delivery; and a range of ICD-9-CM procedure codes describing the method of delivery and other perinatal obstetrical interventions. The maternal abstract also contains information abstracted from the prenatal care record, which is completed by the primary care physician during pregnancy, including a count of the number of prenatal visits (to a maximum of eight or more), the week of gestation in which care was initiated, and risk assessment scores.

The newborn separation abstract was linked to the mother's record. In cases in which the woman gave birth to more than one baby, only one linked mother-infant pair was retained.

Physician claim files. All physician claims for reimbursement of medical care in Manitoba are submitted to the Manitoba Health Services Insurance Plan. When providing prenatal and postpartum care, a physician may bill on a fee-for-service basis, submitting a claim for each care encounter, or submit a single claim for a fixed-fee global tariff that covers all routine care provided in the prenatal and postpartum periods. In this sample, 86.7% of the pregnancies were supervised by physicians claiming the global tariff.

Postpartum referral files. A referral to a public health nurse is made for all women who give birth, with the objective of completing at least one contact following discharge. The referral record contains information obtained during a predischarge interview with the woman in hospital, including attained education, prenatal care and participation in prenatal education classes, smoking status, and infant feeding practices. Files for 806 (6.4%) of the 12 646 women eligible for study could not be located in the postpartum referral database. These women were assigned the status of nonsmokers and the status of enrollees in prenatal education programs.

Public-use census files. In the absence of individual-level measures of socioeconomic status, data from the 1986 Canadian census, aggregated to the geographic unit of the enumeration area, were used to rank neighborhoods in population quintiles by average household income. This approach has been used in previous research using administrative data.[28–34] In Winnipeg, there are approximately 800 enumeration areas containing residential households, with an average population of 700 people. Using the full six-digit postal code, a total of 71 (0.6%) women could not be linked to census information on mean household income and were assigned the sample average.

[c]Complications were identified by ICD-9-CM diagnostic codes 640–644, 646 recorded on either physician claims or hospital abstract. See Table 1 for detailed listing.

Measures

Table 1 summarizes the measures of maternal, newborn, and prenatal care characteristics used in this study.

Pregnancy complications. Complications of pregnancy were identified from ICD-9-CM diagnostic codes 640 through 648 on both physician claims and hospital separation abstracts. On the basis of an analysis of the predictive validity of specific diagnoses in relation to birthweight outcome, six diagnostic categories were retained in the analysis (see Table 1). A woman was classified as experiencing a complication if one or more of these diagnoses were identified on either data source.

Frequency of care. Physicians' services for pregnancy care were classified into two categories: office visits and in-office or laboratory diagnostic tests. Office visits were defined as any claim with ICD-9-CM diagnostic codes for normal pregnancy (V22); supervision of high-risk pregnancy (V23); complication related to pregnancy (ICD-9-CM 640–648); other indications for care in pregnancy, labor, and delivery (ICD-9-CM 650–659); or complications occurring in the course of labor and delivery (ICD-9-CM 660–669).

For the 13.3% of women who received care from physicians who billed on a fee-for-service basis, both the timing of initiation of care and the number of episodes of care could be established directly from the individual claims. However, for the majority of women who received care from physicians billing the global tariff, direct enumeration of service claims was not possible. For these women, direct billing of specified in-office or laboratory diagnostic tests was used as a surrogate measure of the number of episodes of care. The selected tests were glucose monitoring, hemoglobin, urinalysis, Pap smear, and hormonal pregnancy test. The first three tests are the standard monitoring tests in pregnancy.

A comprehensive ambulatory health care history was compiled for each woman in the sample, capturing all instances of use of ambulatory care services in the period from 365 days before birth to 90 days postpartum. Of the 497 062 claims abstracted, approximately 54% were associated with the provision of prenatal or postpartum care and were retained.

Adequacy of care. Length of pregnancy in days was calculated individually for each woman from the measure of gestation period on the hospital record. For the 41 cases (0.3%) with a missing or out-of-range gestation period, a gestation period of 280 days was assigned. A summary measure of prenatal care, defining the adequacy of care relative to an ideal standard, was constructed from measures of the timing of initiation of care, frequency of visits, and the length of gestation.[35] This index, which classifies care as adequate, intermediate, or inadequate, has been used in other settings to adjust for the effects of shortened gestation on the use of prenatal care.[6,10,36]

A series of analyses was performed to examine the agreement between physician claim records and the hospital abstract on measures of utilization of care. A detailed description of these analyses is presented elsewhere.[37] In general, physician claims were found to yield measures of care comparable to those of the hospital abstract. However, the hospital abstract was missing information on the initiation of care for 12.3% of the women and on the number of prenatal visits for 9.2% of the women. In subsequent analyses reported here, measures of use derived from physician claims have been applied exclusively, in contrast to the alternative approach of using physician claim measures only to substitute for missing utilization measures on the hospital abstracts.

Analytic Methods

To assess the effectiveness of prenatal care, we compared pregnancy outcomes across groups of women who received different amounts of care or who initiated care at different points in their pregnancies. In this observational design, there are three methodological obstacles for which no ideal analytic solution exists.[33] The most fundamental problem in comparing outcomes across groups of women with different patterns of utilization is that women who give birth prematurely will most certainly be shown to use less care than women whose pregnancies go to term. A second problem, with an opposite effect on utilization, is confounding by indication: women who experience complications early in pregnancy will be

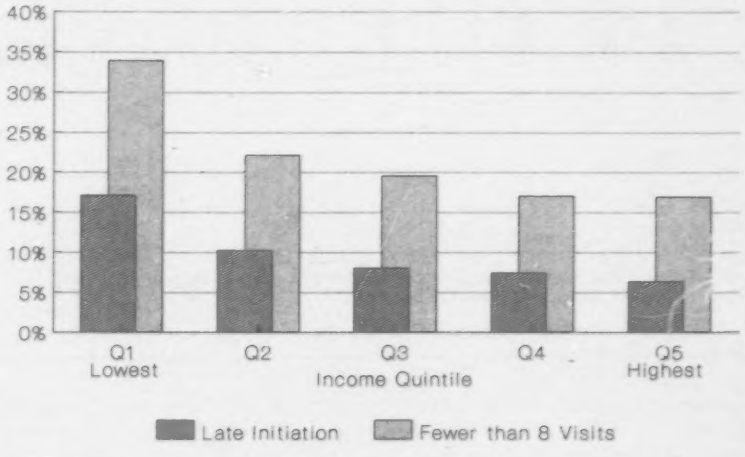
expected to seek medical care earlier and more often than women with an uncomplicated first trimester. The final obstacle to valid inferences about the effect of care on outcome in an observational study is selection bias. The analytic approach of this study was designed to minimize these problems. To reduce the chance of bias due to preterm delivery, we adopted an index of the adequacy of prenatal care that classifies the use of care according to the length of gestation; however, this classification precludes examining the potential effect of prenatal care on pregnancy duration in the absence of fetal weight gain. We also emphasized the ascertainment of pregnancy complications, which permitted statistical adjustment for the influence of complications on use of care. No adjustment for errors of inference due to selection effects is possible in an observational research design.

A chi-square test of association or an *F*-test statistic derived from an analysis of variance was used to examine differences between women in demographic risk factors, prenatal care utilization, and the incidence of complications. The relationship of measures of prenatal care, maternal characteristics, and pregnancy complications to birthweight was examined in two ways: (1) birthweight in grams was regressed on the set of independent variables in a multivariate linear regression analysis and (2) birthweight was classified as a dichotomous dependent variable, with weight less than 2500 g defined as low birthweight in a logistic regression analysis. As the main results of these two models were similar, only the linear regression analyses are reported here.



Note. Late initiation = more than 13 weeks gestation.

FIGURE 1—Initiation of prenatal care and number of visits, by income quintile.

Results

Characteristics of the population, stratified by income quintile, are reported in Table 2. First births accounted for 43.9% of the births. A total of 7% of the women in the study population were younger than 20 years of age. Smoking during pregnancy was reported by 27.6% of the women, 26.5% were unmarried at the time of delivery, 24.1% had experienced a prior pregnancy loss, and a complication in the prenatal period was detected in 25.3% of the pregnancies. Overall, 4.7% of the infants weighed less than 2500 g at birth, and 5.9% of the births occurred before the 37th week of gestation.

Less than adequate care	759	3175	3134, 3217

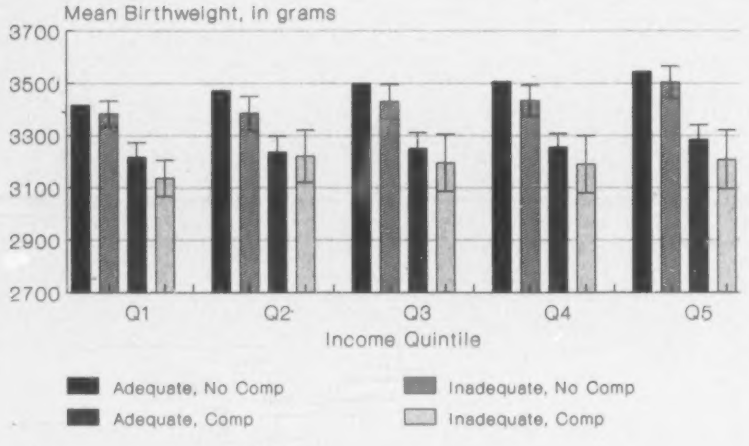

FIGURE 2—Mean birthweight, by income quintile, pregnancy complications (Comp), and prenatal care.

Maternal characteristics were distributed unequally across the five neighborhood income categories. Women residing in the poorest 20% of neighborhoods (quintile 1), compared with women residing in the wealthiest 20% of neighborhoods (quintile 5), were more than twice as likely to report having smoked during pregnancy, were three times as likely to be unmarried, and were four times as likely to be under the age of 20. The crude incidence of low birthweight among women in quintile 1 was 62 per 1000 live births, almost twice the rate observed among women in quintile 5 (35/1000).

Women in the sample had an average of 11.2 visits to prenatal care professionals during their pregnancies (Table 3). A total of 8.2% (1037 women) had fewer than 5 visits, and 14.1% had between 5 and 8 visits. Care was initiated, on average, during the 7th week of gestation; 90% of the women initiated care by the 13th week. In only 2.2% of the pregnancies was the first visit delayed until the third trimester. When utilization was expressed in terms of adequacy of care, 74.3% of the women received adequate care and 8.9% received inadequate care; inadequate care was defined as initiation later than the second trimester (27 weeks) or, in the case of earlier initiation, an insufficient number of prenatal care contacts.

Only marginal differences in utilization were observed among the 60% of women in the three highest income quintiles. However, the 20% of women in the lowest income quintile had consistently and substantially poorer utilization than those in the median- and high-income groups. Poor women had an average of 1.5 fewer visits during their pregnancies and first sought care an average of 1.5 weeks later. A total of 17% of the poorest women initiated care later than the first trimester, compared with less than 7% of the women in the median to high quintiles (Figure 1).

Among uncomplicated pregnancies, infants born to women who received less than adequate care were, on average, 73 g lighter than infants of women receiving adequate prenatal care ($P < .001$, 95% confidence interval [CI] = 47 99) (Table 4). After adjustment for maternal characteristics and income, this difference was reduced to an estimated 55.6 g ($P < .001$, data not shown). In these analyses, prenatal care was dichotomized as adequate or less than adequate. The latter category combines both intermediate and inadequate care.

As expected, the average birthweight of infants born to the 25.2% of women who experienced complications in pregnancy was substantially lower than that of infants born to women with uncomplicated pregnancies (a difference of 244 g; $P < .001$, 95% CI = 185, 301) (Table 4). The complications measured in this study are prevalent in early gestation and are strongly predictive of premature birth.

Among women with complicated pregnancies, only a slight difference in birthweight (72 g; $P < .001$, 95% CI = 31, 114) was observed between the adequate care and less than adequate care groups. The estimated positive contribution of care to birthweight was no greater in complicated pregnancies than in pregnancies without noted complications. As shown in Figure 2, this weak relationship was consistent across all income groups.

In a bivariate analysis, mean birthweight decreased with declining income. Infants born to women in the poorest quintile were, on average, 140 g lighter than infants born to women in the wealthiest quintile (Table 5). The magnitude of birthweight differences associated with income was reduced when maternal factors were included in the analytic model, reflecting the concentration of maternal risk factors such as smoking and single marital status among women living in poor neighborhoods. These income-related differences were further reduced following the addition of variables measuring pregnancy complications and use of prenatal care.

These analyses were repeated after stratifying the population into two groups according to the presence or absence of recorded complications in pregnancy. The

results were similar to those of the unstratified analysis.

Discussion

This study has a number of strengths compared with previous studies of the effectiveness of early and frequent prenatal care. Information on prenatal care utilization, maternal smoking status, the incidence of pregnancy complications, and an indirect measure of socioeconomic status were available for a virtually complete population of urban women giving birth between July 1987 and December 1988.

The study provided a direct test of the hypothesis that prenatal care has the greatest impact on complicated pregnancies. Pregnancy complications were detected in 25.2% of the women in this study, an incidence higher than has typically been reported in other studies. However, the literature describing the incidence of complications in complete populations is poorly standardized, with wide variations in measurement methods, sources of data, and inclusion criteria.[6,10,14,30,38–43] In general, however, complication-specific rates observed in the Winnipeg population are within the ranges reported in other developed country settings. A British study reported a rate of antepartum hemorrhage of 8.8%,[43] which compares well with the rate of 6.9% observed in the Winnipeg population. Incidence rates of pre-eclampsia and pregnancy-induced hypertension have been reported in the range of 6.5 to 6.2 per 100 births[39,43]; these rates agree with the rate of 6.5 per 100 observed in this study.

Utilization of Prenatal Care

The adequacy of the care received by Winnipeg women under a system of universal insurance that includes comprehensive prenatal medical services compares favorably with rates observed in other North American populations.[8] As measured by trimester of initiation of care, access to prenatal care was better for the Winnipeg women than has been reported for typical US samples, and these differences are more pronounced among women of lower socioeconomic status. A total of 82.9% of the poor women in the Winnipeg sample initiated care by the 13th week of pregnancy, compared with 69% of poor women in an urban sample in Washington State[44] and 70% of low-income women not eligible for Medicaid and 62% of Medicaid-insured women in southern California.[14] Despite this favorable comparison, it is clear that universal health insurance does not remove all barriers to access. The Winnipeg women in the lowest income quintile had consistently and substantially poorer utilization of care than did median- and high-income women.

Effectiveness of Prenatal Care

After adjustment for maternal characteristics and early complications of pregnancy, infants born to women receiving less than adequate care were 58 g lighter than infants born to women receiving adequate care. The size of this benefit is much smaller than has been reported in some recent studies, in which adequate

care has been associated with birthweights 157 to 197 g higher than the birthweights of infants born to women with inadequate care.[6,10,41]

The smaller effect of care in the present study may have been due to a number of factors. The Winnipeg cohort may have been healthier than other samples, with a lower rate of unfavorable birthweights. The overall incidence of low birthweight in the Winnipeg sample during the study interval was 47 per 1000 births. A similarly small effect of care on birthweight was reported among women enrolled in a northern California health maintenance organization (HMO), where the rate of low birthweight was 42 per 1000 births.[45] In this HMO population, in which 83% of women initiated care in the first trimester, the estimated contribution of early initiation of care to birthweight, after maternal factors were adjusted for, was 29.9 g. This pattern suggests that the beneficial effects of prenatal care on birthweight become increasingly subtle as the reproductive health of a population improves, and it argues for programs focused on specific populations at high risk.

A surprising and unsettling finding of this study is the absence of a substantial effect of prenatal care on birthweight in complicated pregnancies. The premise of prenatal care is that regular surveillance will enable caregivers to detect the onset of complications and initiate therapeutic responses to mitigate their negative impacts. There is no biological model to suggest any benefit of prenatal medical care in an uncomplicated normal pregnancy. In the management of complications, prenatal care will certainly influence pregnancy outcome in ways not measured by birthweight. At the same time, the absence of a significant impact of care on birthweight in complicated pregnancies in this study provides further evidence of the limited effectiveness of current clinical approaches to the prevention of preterm birth.

The failure to demonstrate a substantial beneficial effect of early prenatal care on birthweight in complicated pregnancies may be due to errors in our analytic approach. Most of the complications examined in this study are strongly predictive of preterm birth. Identification and successful treatment of these complications in the course of prenatal care would result in longer gestation and increased average birthweight. However, the analytic approach used in this study would not be sensitive to interventions that extended the duration of pregnancy, thereby contributing to fetal maturity at birth, but that did not enhance fetal weight gain. It is also possible that the decision to combine a group of discrete complications into a single measure obscured successful complication-specific interventions. Finally, we did not test the hypothesis that prenatal medical care can actually prevent the onset of complications. To the extent that this is a plausible expectation, this study has underestimated the contribution of care by failing to estimate averted morbidity in the group without complications.

In this study, we emphasized the description of socioeconomic differences in the use of prenatal care and in pregnancy outcome. After adjusting for maternal demographic factors, smoking status, complications, and the use of prenatal care, we found a residual difference in average birthweight of 88.8 g between the wealthiest and poorest women in the sample. This unexplained birthweight deficit is larger than can be attributed to the combined effects of complications, smoking, single marital status, and poorer utilization of prenatal care among poor women. Compared with middle-income and wealthy women, poor women experience greater nutritional deficits in pregnancy, may be more likely to be employed in physically demanding occupations, may be exposed more frequently to vaginal infections, and in general have fewer resources with which to respond to the demands of pregnancy.[17,19,46–49] Many of these factors are largely beyond the reach of prenatal medical care.

The findings of this study indicate that the impact of pregnancy complications on birthweight will not be substantially mitigated by improving the utilization of routine prenatal care. After 2 decades of observational studies, the evidence for a beneficial effect of early and frequent prenatal care on birthweight remains ambiguous. To resolve this uncertainty, it has been suggested that researchers conduct randomized trials of specific questions about the organization and delivery of prenatal care.[9,19,50] Without evidence from such definitive studies, the findings of this study do not support the proposition that the route to moderating socioeconomic inequities in birthweight is through improved access to conventional prenatal care. □

Is Breast-Feeding in Infancy Associated with Adult Longevity?

ABSTRACT

Objectives. The purpose of the study was to determine whether breast-feeding is associated with increased longevity or cause-specific survival.

Methods. Teachers throughout California identified intellectually gifted children as part of a prospective study begun in the 1920s by Lewis Terman. Information on breast-feeding was available on 1170 subjects, who have been followed for more than 65 years.

Results. Survival analysis (Cox proportional hazards model) indicated that breast-feeding was associated with increased longevity, even after adjustment for age at baseline, birthweight, infant health, and childhood socioeconomic status, but only among men, and the association was not significant ($P = .15$). Neither cardiovascular disease nor cancer survival was significantly associated with duration of breast-feeding for either sex. Survival from deaths due to injuries was positively associated with breast-feeding after adjustment ($P = .03$) and demonstrated a clear gradient with duration, but only among men.

Conclusions. Overall, the present study does not provide strong evidence that breast-feeding is associated with adult longevity. The reduced risk of death from injury may reflect chance, in that the association was significant only for men, or it may reflect psychosocial correlates of breast-feeding practices. (*Am J Public Health.* 1994;84:1458–1462)

Introduction

The immediate benefits of breast-feeding are well known.[1,2] Breast-feeding increases survival in poor countries and reduces the risk of infant gastrointestinal infections, lower respiratory tract infections, otitis media, bacteremia, and meningitis in all settings. This benefit is most evident in the first 6 months of life, but it persists into the child's second year. Studies of long-term effects have demonstrated that breast-feeding is associated with a lower risk of childhood cancer, especially lymphoma[3]; insulin-dependent diabetes mellitus[4]; and Crohn's disease and ulcerative colitis.[5,6]

In a previous study of mortality rates, men who had been breast-fed as infants and weaned before their first birthday, or who had been both breast- and bottle-fed, had lower ischemic heart disease mortality rates than men who were either exclusively bottle-fed or breast-fed and not weaned before their first birthday.[7–9] In addition, as adults the former group also had lower serum total cholesterol levels, lower low-density lipoprotein (LDL) levels, and lower ratios of LDL to high-density lipoprotein (HDL).[9] Studies in children and young adults indicate that long-term differences in serum cholesterol levels between breast-fed and bottle-fed infants are small and inconsistent.[10] In an experimental study of baboons, animals that had been breast-fed had higher very low-density lipoprotein levels and higher LDL to HDL ratios until adulthood, and more extensive arterial fatty acid streaks as adults, than did animals that had been bottle-fed.[11]

In the present study we examine whether breast-feeding is associated with increased longevity and cause-specific survival in a prospective population-based study, the Terman Life Cycle Study.[12] Data are available on more than 1000 boys and girls born between 1904 and 1915 who have been followed for mortality through 1986.

Methods

Sample

The Terman Life Cycle Study was initiated by Lewis Terman in the 1920s and continued first under the direction of Robert Sears and then Albert Hastorf. Teachers throughout California identified the three brightest children and the youngest child in their classrooms for testing. This yielded a sample of 1528 children (856 boys and 672 girls) who were identified as gifted. This sample is fairly homogeneous on intelligence (bright), race (White), and social class (mostly middle).[13]

The present analyses were restricted to the 1373 subjects who were born

TABLE 1—Percentage Distribution of Breast-Feeding Duration, by Infant's Sex: Subjects in the Terman Life Cycle Study

Breast-Feeding Duration	Boys (n = 647)	Girls (n = 523)
No breast-feeding	10.7	8.8
1–5 mo	22.6	25.2
6–11 mo	34.6	34.6
12+ mo	32.2	31.4
Mean (range)	8.2 (0–24)	8.0 (0–36)

TABLE 2—Distribution of Potentially Confounding Variables, by Breast-Feeding Duration and Sex: Subjects in the Terman Life Cycle Study

Breast-Feeding Duration	Baseline Age, y		Birthweight, lb		Socioeconomic Status[a]		Poor or Fair Infant Health	
	Mean	SD	Mean	SD	Mean	SD	No.	%
Boys (n = 639)								
No breast-feeding	11.5	2.8	8.3	1.6	0.01	0.85	22	31.9
1–5 mo	11.1	2.8	8.2	1.4	0.02	0.80	41	28.9
6–11 mo	11.5	3.1	8.4	1.5	0.08	0.87	36	16.1
12+ mo	12.2*	3.0	8.5	1.5	−0.21	0.85	23	11.4***
Girls (n = 519)								
No breast-feeding	11.1	2.8	7.4	1.5	0.03	0.80	9	20.0
1–5 mo	11.0	2.9	7.8	1.1	0.07	0.87	23	17.8
6–11 mo	10.9	2.8	8.0	1.6	0.09	0.80	13	7.3
12+ mo	11.8	2.8	8.1**	1.5	−0.37**	0.85	11	6.8***

Note. Data were missing on birthweight for 15 boys and 15 girls, on socioeconomic status for 3 boys and 3 girls, and on infant health for 11 boys and 9 girls. *P* values were determined by testing for linear trend based on a linear contrast in an analysis of variance (means) or Mantel-Haenszel chi-square test for trend (percentages).

[a]Parents' education and occupation were standardized to a mean of 0 and a variance of 1 and then averaged. Postive values indicate a higher socioeconomic status, and negative values indicate a lower socioeconomic status.

*$P < .05$; **$P < .01$; ***$P < .001$.

between 1904 and 1915, inclusive (average birth year 1910), to avoid possible cohort effects and to be comparable with our other publications on this data set. Of these participants, 25 dropped out of the Terman study before 1930 and are excluded from the analysis. The 104 subjects lost to follow-up after 1930 are included in the survival analyses up to their date of last contact. A total of 178 subjects were missing information on breast-feeding, resulting in a final sample size of 1170 (647 males, 523 females). Mean age at baseline (approximately 1922) was 11.7 years for the boys and 11.2 years for the girls.

Variables

In the first assessment, parents answered the question, "If child was breast-fed, from what age to what age?" The answers were recorded in months. For the present analyses, the number of months breast-fed was recoded into four roughly equal categories that represent natural cutpoints frequently used in other breast-feeding research (0, 1–5, 6–11, and 12–36 months). At this time, parents also reported their child's year of birth, birthweight, the father's occupation, and the highest grade of school each parent had completed. Parents' education and occupation were standardized to a mean of 0 and a variance of 1 and then averaged to obtain an estimate of the family's socioeconomic status. Positive values indicate a higher social class, and negative values indicate a lower social class; however, the absolute range was narrow and most subjects were in the middle social class.

Parents were also asked to describe their child's health during his or her first year of life. On the basis of these descriptions, the Terman research group rated the child's infant health on a 5-point scale (1 = very poor, 2 = poor, 3 = fair, 4 = good, 5 = very good). For the present analyses, this variable was dichotomized by collapsing ratings 1 through 3 and ratings 4 and 5.

At the first visit, one or both of the subject's parents (if one, usually the mother) and the subject's teacher were asked to rate the subject on 25 trait dimensions. Through factor analysis, six personality dimensions have been identified: conscientiousness, cheerfulness, high motivation/self-esteem, sociability, high energy, and permanency of moods. The first two dimensions are significantly associated with adult longevity.[14]

Surviving subjects were contacted every 5 to 10 years. Death certificates were obtained for the deceased and coded for underlying cause of death by a certified nosologist, using the ninth revision of the *International Classification of Diseases*.[15] Cardiovascular disease deaths were those coded 400–448; coronary heart disease included codes 410–414; cancer included codes 140–239; and injury (both intentional and unintentional) included codes 800–998. For 100 of the 449 deceased subjects, no death certificates were obtained. Physicians' review of information from next of kin allowed classification of 65 of these deaths into broad categories of causes, including cardiovascular disease, coronary heart disease, cancer, and injury. Cause-specific analyses including and excluding these latter deaths indicated no difference in findings; therefore the cause-specific analyses presented use all available information.

Analyses

The sex-specific association between breast-feeding duration and potentially confounding variables was assessed by means of linear contrasts in analysis-of-variance models (for age at baseline, birthweight, and childhood socioeconomic status) and the Mantel-Haenszel chi-square test for trend (for infant health). The association between breast-feeding duration and infant health was also assessed with logistic regression analysis, with and without control for age at baseline, birthweight, and childhood socioeconomic status. The sex-specific association between breast-feeding and personality traits, as a possible mechanism for any association with longevity, was assessed with analysis of variance.

Breast-feeding and breast-feeding duration were used to predict longevity from baseline until 1986 by means of survival analysis (Cox proportional hazards model).[16] The group with any breast-feeding and those in each category of breast-feeding duration were compared with the non–breast-feeding group. The analyses, conducted for all causes as well as specific causes of death, were conducted separately for males and females,

TABLE 3—Total and Cause-Specific Mortality Rates (%), by Breast-Feeding Duration and Sex: Subjects in the Terman Life Cycle Study

Breast-Feeding Duration	All Causes		Cardiovascular Disease		Cancer		Injury		Other	
	Males (n = 284)	Females (n = 165)	Males (n = 90)	Females (n = 37)	Males (n = 88)	Females (n = 52)	Males (n = 42)	Females (n = 17)	Males (n = 43)	Females (n = 45)
No breast-feeding	53.6	32.6	13.6	6.5	18.2	4.4	15.2	6.5	4.6	15.2

Note. Data were missing on cause of death for 20 males and 13 females and on the control variables for 25 males and 25 females. *P* values are for the breast-feeding category shown compared with no breast-feeding, based on Cox proportional hazards model.
[a]Adjusted for age at baseline, birthweight, infant health, and childhood socioeconomic status.
*P = .11–.15; **$P \leq .05$; ***$P \leq .01$; ****$P \leq .001$.

with and without control for age, birthweight, infant health, and childhood socioeconomic status. No adjustments were made for multiple comparisons; rather detailed *P* values are presented. All *P* values are for two-tailed tests.

There were 276 siblings, representing 105 families, within the sample. Analyses restricted to only one sibling per family yielded similar results; therefore, only analyses of the entire sample are presented.

Results

Of the 1170 subjects, 69 boys (10.7%) and 46 girls (8.8%) had never been breast-fed. As can be seen in Table 1, the distribution of total duration of breast-feeding did not differ significantly by sex. The total number of months subjects were breast-fed ranged up to 24 months for boys (mean = 8.2) and up to 36 months for girls (mean = 8.0).

The distribution of potentially confounding variables of the breast-feeding and longevity analysis is presented in Table 2 by breast-feeding duration. A trend analysis is significant for age for males and for birthweight and socioeconomic status for females. Of these variables, only birthweight demonstrates a clear gradient with breast-feeding duration. The significant association for age reflects sample size more than a strong association, and the significance for socioeconomic status reflects the difference in one category more than a trend across breast-feeding categories. Table 2 also demonstrates that among infants who survived to childhood or adolescence, breast-feeding was associated with better infant health among both boys and girls, with a clear gradient of better health with increasing duration of breast-feeding. After adjustment for differences in age, birthweight, and childhood socioeconomic status, variables that might influence both breast-feeding practices and health, the association with better infant health remained significant for boys and nearly reached significance for girls. The odds ratio of having poor or fair infant health for those never breast-fed compared with those breast-fed for 12 or more months was 4.00 ($P < .001$) for boys and 2.38 ($P \approx .10$) for girls. These odds may reflect a causal association or the possibility that sick infants were less likely to be breast-fed. An analysis of breast-feeding

duration and each of the six personality traits (not shown) demonstrated no significant associations.

By 1986, 284 of the men (43.9%) and 165 of the women (31.5%) had died. Total mortality rates were lower among men, but not women, who had ever been breast-fed compared with those who had not, but they did not vary systematically with breast-feeding duration for either sex (Table 3). Of the men, 90 had died from cardiovascular disease (55 of these from coronary heart disease), 88 from cancer, 42 from injury, and 43 from other causes. Of the women, 37 had died from cardiovascular disease (15 from coronary heart disease), 52 from cancer, 17 from injury, and 45 from other causes. Cause of death was unknown for 21 men and 14 women. Cause-specific mortality rates demonstrated that only the association between duration of breast-feeding and deaths from injuries was consistent between men and women.

Table 4 presents the survival analysis over the average 65 years of follow-up for breast-feeding and breast-feeding duration, adjusted for differences in age at baseline as well as birthweight, infant health, and childhood socioeconomic status. Although longer overall survival was associated with any breast-feeding for men in this analysis (relative hazard = .75), the difference was not statistically significant when adjusted for age or other covariates ($P = .15$) and there was only a weak association with duration. The opposite association between breast-feeding and survival for women did not approach statistical significance.

Breast-feeding was not associated with survival from cardiovascular disease for either sex. This was true both before and after adjustment for differences in age at baseline, birthweight, infant health, and childhood socioeconomic status. Similarly, no association was seen for coronary heart disease (data not shown). Although breast-feeding was associated with increased survival from cancer for men and decreased survival for women, the association was not significant for either sex, and there was no significant association with duration either before or after adjustment for potentially confounding variables. Breast-feeding was associated with increased survival from injury for men ($P = .03$), with a clear and significant gradient of longer survival with increasing duration of breast-feeding. Women who had been breast-fed for 12 months or longer also had longer survival ($P = .11$), although this association did not approach statistical significance after full adjustment.

Discussion

In the present study, we found a weak association between breast-feeding and increased longevity among men before and after adjustment for age, birthweight, infant health, and childhood socioeconomic status. Likewise, there was only a weak association with duration of breast-feeding. No association was found among women. Neither cardiovascular disease nor cancer survival demonstrated a significant association with duration of breast-feeding for either sex. Survival from deaths due to injury, however, was positively associated with breast-feeding among men, before and after adjustment for potentially confounding variables, and demonstrated a significant gradient with duration of breast-feeding.

The lack of an association between breast-feeding and subsequent cardiovascular or coronary heart disease survival is contrary to the findings of Barker and colleagues.[7–9] In their study, 5654 men born in England between 1911 and 1930 were traced for mortality between 1951 and 1987 (ages 20 to 74 years). Standardized mortality ratios indicated that men who had been breast-fed had lower ischemic heart disease mortality rates than men who had been bottle-fed (standardized mortality ratios of 81 and 94, respectively).[7] Subsequent analyses in a subset of 485 men indicated that the benefit occurred only among men who had been both breast- and bottle-fed or breast-fed and weaned before their first birthday (standardized mortality ratios of 73 and 79, respectively) compared with men who had been breast-fed and not weaned (standardized mortality ratios = 97) or bottle-fed exclusively (standardized mortality ratios = 95).[9] The results were not adjusted for differences in socioeconomic status. Differences between these two studies may reflect cultural differences between breast-feeding in England and the United States in the early 1900s (i.e., differences in supplementation with bottles, the timing of addition of solid food, or the association of socioeconomic status with breastfeeding practices). Alternatively, the differences may be due to sample sizes or chance.

In the subset of men born in England,[9] those who had been breast-fed and weaned before their first birthday and those who had been both breast- and bottle-fed (i.e., those who had the lowest risk of death from ischemic heart disease) had lower serum total cholesterol, LDL levels, and ratios of LDL to HDL as adults than did men who had been breast-fed and not weaned before their first birthday or who had been exclusively bottle-fed. A study of 30-year-olds found that women who had been breast-fed as infants had lower levels of total cholesterol than women who had been bottle-fed, by an average of 20 mg/dL. The difference among men, however, was only 2 mg/dL.[17] Differences in serum cholesterol levels are small and inconsistent when comparing children and young adults who were breast-fed or bottle-fed as infants.[10] A recent study of 3- to 4-year-old children found no association between breast-feeding duration and diastolic or systolic blood pressure and only a weak positive association with resting heart rate.[18]

There has been no previously published finding of an association between breast-feeding and lower risk of death from injury. The lack of a strong association among women may indicate that the association among men is due to chance; however, women who had been breast-fed for 12 or more months also demonstrated a reduction in risk, although it was not significant. Perhaps mothers who breast-fed in the early 1900s developed stronger psychosocial ties with their children (especially sons), which in turn better prepared the children to interact with others and thereby avoid both suicide and homicide. Perhaps mothers who breast-fed their infants were more safety conscious and therefore raised children who were less prone to accidents. Or perhaps some children (that is, those who were more docile) were both more likely to breast-feed longer and less likely to take chances as they got older. However, in the present study we found no association between being breast-fed and conscientiousness or any other personality trait measured in childhood.

The present sample is restricted to intellectually gifted children from predominantly middle-class families, who tended to become high achievers.[13] Therefore, these findings may not be generalizable to the entire population. However, because of the nature of this sample, several potentially confounding influences can be ruled out. For example, any association between breast-feeding and longevity is probably not confounded by access to medical care, given that the sample was largely middle-class. Recall

bias is also unlikely, because the breast-feeding information was provided by the parent, on average within 10 years of birth and long before the subject's death. It is unlikely that infant health was a confounding factor, for several reasons: all analyses were adjusted for infant health status; only children who survived infancy and early childhood were included in the sample; and in the early 1900s, children too sick to nurse were less likely to survive and to be subsequently identified as intellectually gifted.

The present analysis focused on whether breast-feeding in the early 1900s was associated with adult longevity. Only children who survived infancy and early childhood were included in the sample; therefore, associations do not reflect known associations with early mortality but only those with adult longevity. Although breast-feeding practices have changed over time, any biologically mediated association should still be evident.

Overall, the present study does not provide strong evidence that breast-feeding is related to adult longevity. The association of breast-feeding with deaths due to injury among men may be due to chance alone or to psychosocial correlates of breast-feeding practices. □

Harsh Social Conditions and Perinatal Survival: An Age-Period-Cohort Analysis of the World War II Occupation of Norway

Allen J. Wilcox, MD, PhD, Rolv Skjærven, PhD, and Lorentz M. Irgens, MD, PhD

ABSTRACT

Objectives. The hypothesis was tested that unfavorable social conditions are associated with poor perinatal survival through direct effects on pregnancy or, more indirectly, through effects on mothers born under such conditions. The occupation of Norway by Nazi Germany was used as a period of social hardship.

Methods. Data from Norwegian vital statistics and the Medical Birth Registry were used to describe perinatal mortality during World War II and also a generation later, among babies born to mothers who had themselves been born during the war. Logistic regression was used to identify a possible cohort effect among mothers born in 1940 through 1944 compared with mothers born before or after that period.

Results. Harsh conditions in Norway during the occupation increased childhood mortality. However, perinatal mortality declined during that period. Likewise, no adverse effect was seen on the survival of babies born to mothers who had themselves been born during the war (odds ratio = 1.00; 95% confidence interval = 0.96, 1.04).

Conclusions. We find no evidence that wartime conditions in Norway impaired perinatal survival, either directly or through an effect on women born during the war. These data underscore how little is known about the ways that social conditions influence perinatal mortality. (*Am J Public Health.* 1994;84:1463–1467)

Introduction

In this century, rates of perinatal mortality have fallen steeply in Norway, as they have in all developed countries. The precise causes of this secular decline are unclear; however, there is general agreement that broad improvements in living conditions, nutrition, and public health have contributed.[1] A similar decline in perinatal mortality took place a century earlier among the European aristocracy, before the era of modern medical care.[2] This supports the hypothesis that social factors make sizable contributions to perinatal survival.[3]

Social conditions may have immediate or delayed influence on perinatal survival. Some factors may act directly, around the time a woman becomes pregnant and gives birth (a period effect). Severe malnutrition is a well-documented example of such an effect.[4,5] Other factors (perhaps including nutrition) may accumulate over the lifetime of the mother (a cohort effect). As a specific type of cohort effect, some authors have hypothesized that a woman's earliest experience as a fetus and young child contributes to her ultimate reproductive success.[6–8] Although all these hypotheses have some plausibility, the usual vital-statistics data offer little basis for preferring one interpretation over another. Without conclusive evidence, the common assumption is that an infant's survival is most strongly affected by conditions prevailing at the time of its fetal development and birth.[9,10]

An historical event may shed light on this issue. In 1940, Norway was invaded and occupied by Nazi Germany. For the next 5 years, the Norwegian population was subjected to severe food shortages and other disruptions. We looked for immediate and delayed effects of those harsh social conditions on perinatal health.

Methods

We drew on two sources of Norwegian perinatal data. One is the published tables of vital statistics, which include annual rates of infant mortality since 1836.[11] We present perinatal and childhood mortality rates for a 50-year period including World War II (1921–1970). Those data are straightforward and require no special analysis.

The second source of data is the Medical Birth Registry of Norway. The Medical Birth Registry comprises all births (including fetal deaths with gestational ages of 16 weeks or more) recorded in Norway since 1967. The annual number of births in the registry has ranged from 50 000 (in 1983) to 69 000 (in 1969), totaling 1.45 million births through 1991. All infant deaths are routinely linked to the birth registry by using the national identification number. The registry includes mother's birth date, from which her birth cohort and age at delivery can be determined.

Mothers with babies in the Medical Birth Registry were themselves born over a range of years that spans World War II. To carry out an analysis of births among

the cohort of mothers born during the war, births in the Registry were categorized into 5-year maternal birth cohorts (<1925, 1925–1929, 1930–1934 . . . 1965–1969, 1970–1974, and 1975+), as well as by the year of the baby's birth, also in 5-year time periods (1967–1971, 1972–1976, 1977–1981, 1982–1986, and 1987–1991). Five-year categories for birth periods and maternal birth cohorts define maternal-age groups that correspond approximately—but not precisely—to 5-year categories. This feature of cohort analysis has been clearly described by Case.[12] For example, births in 1967 through 1971 to women born in 1940 through 1944 will be chiefly to women aged 25 through 29 years, but will include some women as young as 23 or as old as 31. Although it is not always discussed explicitly in age-period-cohort analyses, imprecision is inherent in the grouping process. We note this imprecision by designating each maternal-age category according to its central year, for example as "age 27" rather than as "ages 25 through 29."

In the cohort analysis, we first looked separately at stillbirths and at early neonatal deaths (deaths in the first week of life). Results were similar for the two outcomes, and so these two categories of death were combined as perinatal mortality. Rates for mothers younger than 15 or older than 44 years are not included because of instability due to small numbers.

It is a property of age-period-cohort data that when any two of the three variables are fixed, the third is determined. Thus, period and cohort effects are inherently dependent on each other, and no simple solutions are available to separate them.[13] Determination of a possible effect through a specific cohort can be approached as follows. First, we used a logistic regression analysis to model the general effects of birth period and maternal age (as categorical covariates) on perinatal mortality.[14] This simple model provided a reasonable fit to the whole data set ($\chi^2 = 22.8$, 20 *df*, $P = .30$). A single linear (or "drift") term for the period effect reduced the goodness of fit considerably ($\chi^2 = 86.5$, 34 *df*, $P < .01$).[15]

To test for a specific cohort effect in women born during the war, a "dummy" variable was created comprising the five period-age combinations that correspond to the war cohort. This dummy variable includes one data point from each relevant period or, equivalently, one data point from each relevant maternal-age group. The overall effects of age and period were then reestimated for the whole data set excluding the dummy cohort variable. Finally, the possible influence of the war cohort variable (in addition to the effects of age and period) was assessed by likelihood ratio tests.[14] Seen another way, this process estimated a cohort time trend based on all cohorts born before or after World War II, and then measured any deviance of the war cohort from the expected trend. For completeness, the same test was performed separately on each birth cohort.

Results

Mortality rates for Norwegian infants and children from 1921 through 1970 are shown in Figure 1. Mortality is on a log scale to accommodate the wide range of rates. Death rates declined in all categories by at least 50% during the time period. The most striking effects of World War II were among children over 1 year of age. Within each age category of childhood mortality, the death rate increased by at least a third and then fell in the next time period to below prewar levels. These patterns were consistent for both boys and girls and for deaths due to accident as well as illness (data not shown). For postneonatal mortality (deaths between 1 month and 1 year of age), the overall decline was interrupted only slightly during the war years. There is no evidence for any effect of World War II on the decline of perinatal mortality (stillbirths plus deaths in the first week of life).

Table 1 presents data from the Medical Birth Registry on births among mothers who were born from 1920 through 1974, the same general time period as Figure 1. Data are sorted by age of the mother, birth cohort of the mother, and period of the birth. Columns correspond to maternal age, horizontal rows show the mother's birth cohort, and diagonals (lower left to upper right) show the time period during which the index birth occurred. Table 2 presents perinatal death rates (per 1000) within the same groups. Declining mortality rates are apparent with advancing period and cohort. Risk is elevated among the youngest and oldest mothers.

1987–1991							

Note: Horizontal rows show mother's birth cohort, and diagonal rows (lower left in the first column of the table to the last column under "Maternal Age") show the period during which the index birth occurred.

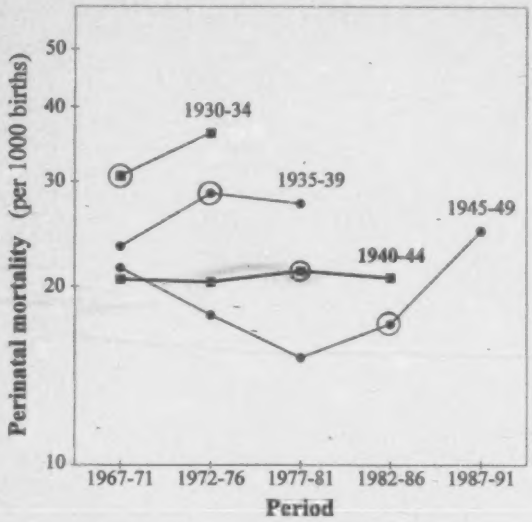
The decline in perinatal mortality seen in Figure 1 has continued throughout the subsequent 25 years covered by the registry. Figure 2 shows perinatal mortality among four birth cohorts of women, arranged by the time period in which their pregnancies occurred. Two cohorts were born before World War II, one was born during the war, and the fourth was born immediately after. There is a general pattern of decreasing mortality within each successive cohort, although this pattern is complicated by maternal age. In any given year, women from different birth cohorts also differ in age. As an illustration of this, the perinatal mortality for mothers in the 37-year age group is circled on each cohort curve. Figure 3 shows the cohort curves for all birth cohorts arranged by mother's age.

Our hypothesis was that the babies of women born in 1940 through 1944 would have higher perinatal mortality than that predicted from the cohorts of mothers born before and after the war. We used an analytic approach that tested whether the experience of the war cohort differed from the overall pattern of steadily improving mortality in successive cohorts. After modeling the general effects of age and period, the odds ratio for the war cohort was 1.00 (95% confidence interval = 0.96, 1.04). Thus, we found no evidence that being born during World War II impaired women's ability to bear healthy infants.

We carried out the same analytic procedure on the other birth cohorts represented in the registry. Odds ratios for these cohorts ranged from 0.99 to 1.02, with tight confidence intervals due to the large number of births within each cohort. The reproductive success of each cohort of mothers is what would be predicted by the observed mortality trends associated with period and age.

Of course, this analytic approach cannot distinguish the relative contributions of period and cohort to perinatal mortality; it shows only that when taken one at a time, no single maternal cohort deviates from the pattern set by all other cohorts in the sample. Another limitation of this test is that it does not consider



Note. Circles indicate mortality for mothers with a central age of 37 years.

ways in which mortality patterns *within* cohorts might differ. For example, the war cohort (1940–1944) has a relatively flat pattern of perinatal mortality with advancing age compared with other cohorts. The meaning of this pattern, if any, is unclear.

Discussion

Perinatal mortality is continuing to decline in many countries, which is an expression of improvements in social and other factors that determine perinatal risk. Within this pattern of general improvement, large differences in perinatal mortality by socioeconomic status persist. How important are social conditions around the time of pregnancy or conditions earlier in the life of the mother? Norwegian data allow both factors to be studied in relation to the hardship of World War II. During World War II, the Norwegian population suffered not only deprivation of food and other essentials, but also punishment for resistance to German occupation. Many were imprisoned, and war-related deaths are estimated at about 10 000.

We looked for wartime effects on perinatal mortality during that time and also a generation later, when women born during the occupation themselves gave birth. Data for the latter group of births are not routinely available; vital statistics do not link the mother's age with survival of her infant, and so perinatal outcomes for maternal birth cohorts must be constructed from other sources. The Medical Birth Registry of Norway provides the mother's age linked with perinatal mortality for a recent 25-year period and includes many mothers born during World War II.

We were able to find no evidence that Norway's experience during World War II affected perinatal survival, either immediately or through indirect effects on mothers born during the war. These data do not contradict previous reports of increased perinatal death associated with maternal starvation. Maternal malnutrition appears to impair perinatal survival when caloric intake falls below a certain threshold,[5] and extreme malnutrition was rare in Norway. However, the disruption and distress that accompanied German occupation are unquestioned, and the absence of measurable effects on perinatal mortality raises several possible interpretations.

1. Deaths may have been incompletely registered during this period, especially fetal or early infant deaths. By 1940, the registry of perinatal deaths had been routine in Norway for a century. We know of no evidence to suggest that registration deteriorated during the war; still, that possibility cannot be ruled out. Underregistration of deaths might have contributed to the absence of a direct war effect on perinatal mortality; it would not account for the absence of an effect a generation later.

2. Pregnant women and infants may have been relatively protected from the hardships of the occupation. It is difficult to reconstruct all aspects of this disrupted period of history, now a half-century in the past. Norway was not self-sufficient in food production; during the blockade of imports in 1942 through 1945, severe undernutrition and frank malnutrition were commonplace.[16] Pregnant women and infants probably did not suffer the worst; however, deprivation was widespread. Young children were not spared, as suggested by their mortality rates (Figure 1). Childhood growth retardation and delay of menarche during this time have been documented.[17,18] Because conditions were most severe in the last part of the war, we carried out additional analyses in 3-year groupings, separating the 1940 through 1942 cohort from the 1943 through 1945 cohort. Results were unchanged; no cohort effect was apparent in either group.

3. To produce a cohort effect on reproduction, hardship may have to come

later in childhood, or be sustained over a longer time. Logistic regression analysis of data from cohorts of women who were born before the war (and thus were older children at the time of the war) showed no evidence of adverse effects on their later reproduction. Possible effects of more prolonged deprivation cannot be evaluated with these data.

4. War conditions may have discouraged some high-risk women from becoming pregnant, thus concealing adverse wartime effects on those pregnancies that actually occurred. Maternal age at delivery did not change in Norway between 1935 through 1939 and 1940 through 1944.[9] Furthermore, Norwegian age-specific fertility rates were actually higher during the war than in the previous 5-year period.[9] Thus, we find no gross evidence of self-selection for pregnancy related to the war. The influence of more subtle selection among women who became pregnant is difficult to assess.

5. Perinatal mortality may be too crude an end point; period or cohort effects may be detectable only among less drastic outcomes such as fertility or fetal growth. Fertility or fetal growth effects may occur[19] but are not directly relevant to the present analysis. The object here was to explore connections between social conditions and perinatal survival.

Some additional data are available from Holland, which also had severe wartime experience. Parts of Holland suffered extreme deprivation during the German occupation. Famine occurred in some regions between October 1944 and May 1945. Pregnant women who were starved in their first trimester experienced increased rates of stillbirth, whereas those who were starved late in pregnancy had increased rates of infant death in the first 3 months of life.[5] Subsequent cohort effects on perinatal survival of babies born to these Dutch women have been suggested but are not well documented.[20] Unlike the experience in Norway, national rates of postneonatal mortality in Holland jumped sharply during the war to more than double the prewar level.[21] However, national rates of perinatal mortality declined for Holland, as they did in Norway.[21]

Maternal age, birth period, and maternal birth cohort are not isolated variables, of course. For instance, maternal age is correlated with parity, and parity is in turn affected by desired family size and selective fertility,[22] which change with time. These and other variables may be relevant to the interpretation of period and cohort effects, but they are beyond the scope of the present analysis.

In conclusion, we looked for increases of perinatal mortality specifically related to the occupation of Norway by Nazi Germany during World War II. Whereas mortality increased for children during the war, there was only a slight effect on postneonatal deaths and none on perinatal deaths. We found no evidence that women who were born during the war suffered later consequences in their ability to bear viable infants. Our inability to detect wartime effects underscores how little we understand the ways in which social factors act on perinatal mortality. □

State Family Planning and Abortion Expenditures: Their Effect on Public Health

Kenneth J. Meier, PhD, and Deborah R. McFarlane, DrPH, MPA

ABSTRACT

Objectives. This study examines whether state family planning expenditures and abortion funding for Medicaid-eligible women might reduce the number of low-birthweight babies, babies with late or no prenatal care, and premature births, as well as the rates of infant and neonatal mortality.

Methods. Using a pooled time-series analysis from 1982 to 1988 with the 50 states as units of analysis, this study assessed the impact of family planning expenditures and abortion funding on several public health outcomes while controlling for other important variables and statistical problems inherent in pooled time-series studies.

Results. States that funded abortions had a significantly higher rate of abortions and significantly lower rates of teen pregnancy, low-birthweight babies, premature births, and births with late or no prenatal care. States that had higher expenditures for family planning had significantly fewer abortions, low-birthweight babies, births with late or no prenatal care, infant deaths, and neonatal deaths.

Conclusions. Funding abortions for Medicaid-eligible women and increasing the level of expenditures for family planning are associated with major differences in infant and maternal health in the United States. (*Am J Public Health.* 1994;84:1468–1472)

Introduction

Except for the obvious impact on maternal mortality,[1] the debate over government funding for abortions has seldom focused on public health. Instead, the arguments usually pit the equal rights of poor women to control their own bodies against the rights of those taxpayers opposed to abortion. Currently, the Hyde amendment prohibits the federal government from funding abortions except in cases of incest or rape.[2] (Recent proposed regulations would require states to fund abortions under these conditions.) States, however, may use their own funds to pay for abortions for Medicaid-eligible women, and 12 states currently do so.

Previous studies suggest that the availability of both abortion and family planning services produces public health benefits. Grossman and Jacobowitz found that increased access to legal abortion was the most important factor in the large decreases in US neonatal mortality from 1964 to 1977[3]; the second most important factor was subsidized family planning services for poor women. In a subsequent study, Corman and Grossman reported that increased availability of abortion was by far the most important factor in the decline in Black neonatal mortality[4]; for Whites, however, abortion availability was only the fifth leading contributor to lower neonatal rates. Abortion affects neonatal mortality by reducing the number of unwanted births. Because unwanted births are less likely to receive early prenatal care and may be linked to low birthweights,[5–8] access to abortion should be indirectly associated with earlier prenatal care and fewer low birthweights. Both reduce neonatal mortality. (It has been found that Medicaid restrictions on abortion funding increase the probability of birth but have no impact on birthweights.[8])

A 1984 study found that states that did not have public funds available to pay for abortions for low-income women had to spend more money "to provide maternity care, medical care for the infant, Aid to Families with Dependent Children, and nutritional assistance to women on Medicaid."[9(p111)] For every dollar used to pay for abortions for poor women, the study found that more than $4 were saved in medical and social welfare costs over the next 2 years.[9]

The primary purpose of this paper is to examine whether state funding for abortions and family planning from 1982 to 1988[10] actually produced public health benefits. Both policies attempt to reduce unwanted pregnancies so that a larger percentage of the pregnancies that are carried to term are wanted. This should reduce prenatal problems and result in healthier babies.

Data Sources and Methods

Dependent Variables: Public Health Impacts

State abortion rates—the number of abortions per 1000 women aged 15 to 44—were obtained from the Alan Guttmacher Institute.[11,12] To provide estimates for 1983 and 1986, when the institute did not collect data, the McFarlane and

Kenneth J. Meier is with the Department of Political Science at the University of Wisconsin–Milwaukee. Deborah R. McFarlane is with the University of New Mexico, Albuquerque.

Editor's Note. See related editorial by Klerman and Klerman (p 1377) in this issue.

Meier procedure was used.[13] For 1983 data, the ratio of abortions reported to the Centers for Disease Control (CDC) in 1983 to those reported in 1982 was calculated for each state. This procedure assumes that CDC abortion data, while biased, are biased consistently from year to year. This ratio, the state's annual growth rate in abortions, was then multiplied by 1982 abortion data from the institute to estimate the number of abortions in each state for 1983. These figures were then converted into rates by dividing them by the number of women aged 15 to 44 (in thousands) in that state. Similar estimates for 1986 were constructed using 1985 and 1986 CDC data.

All other dependent variables were taken from the National Center for Health Statistics for the years 1982 through 1988. These measures are the teen birthrate (number of births to women under age 20 per 1000 women aged 14 to 19), the percentage of low-birthweight babies (<2.5 kg), the percentage of premature births (<37 weeks of gestation), the percentage of births with late or no prenatal care (defined as starting after the first trimester of pregnancy), the infant mortality rate (number of infant deaths per 1000 live births), and the neonatal mortality rate (number of deaths to infants <28 days old per 1000 live births).[14]

Independent Variables

The two major variables of interest are policies to fund abortions for Medicaid-eligible women and policies that fund family planning services for low-income women. The measure of abortion funding policy is the funded abortion rate—that is, the number of publicly funded abortions in the state per 1000 women aged 15 to 44.[15] The per capita family planning expenditures measure includes all federal (Titles V, X, XIX, and XX) and state funds.*[16,19]

Public policies toward funding abortions and family planning are not the only factors that influence maternal and child health; numerous socioeconomic factors do also. Precise estimates of the respective impacts of abortion funding and family planning policies on maternal and child health require that these other factors be included as control variables. For example, teen pregnancy rates and proportions of children who are born into poverty (and thus have more severe health problems) are higher among non-White women. Black women are also less likely to receive adequate prenatal care.[20] In addition, Henshaw et al. found that the abortion rate is 2.7 times higher for non-White women than for White women.[21] Black women are much more likely than White women to have an unwanted birth.[7] Latino women also have higher abortion rates than non-Latino women.[22] These relationships necessitate including the Black and Latino population percentages in the model. (Data are from the Bureau of the Census, *Statistical Abstract of the United States,* for various years. For the Latino population, individual years had to be extrapolated from the 1980 and 1990 census data.)

States with fewer poor women will have fewer birth-related problems.[23] Abortion rates are also related to income; Medoff found that demand for abortions is positively related to the labor force participation of women.[24] For this reason, the percentage of women in the labor force and per capita income are also included in the model.

A proxy measure of pro-life attitudes in a state—the percentage of the state that is Catholic—is included.[25] The Catholic church has actively supported right-to-life groups and opposes abortion and most birth control methods.[15] A negative relationship between the proportion of Catholics in a state and the rate of abortions was expected.

One final control variable is access to abortion providers. Shelton et al. found that the farther a woman must travel to obtain an abortion, the less likely she is to get one.[26] The availability of abortion services varies widely across the United States; more than 30% of women of reproductive age live in counties with no abortion provider.[11] Owing to the expected positive relationship between access to providers and the abortion rate, the percentage of a state's population living in counties with large providers of abortion is included as a control variable.

Methods

The analysis is a pooled time series of all US states from 1982 to 1988. Each dependent variable was examined as the result of the six control variables as well as the funded abortion rate and family planning expenditures. A pooled time-series design is often plagued by problems of autocorrelation and heteroscedasticity.[27,28] Although the current data set is cross-sectionally dominant, preliminary analysis revealed that first-order autocorrelation was the major problem. This problem dictated that all models would be estimated using generalized least squares-autoregressive moving average models without forced homoscedasticity. After initial model estimation, residuals were examined to determine if significant fixed effects were omitted from the model. As would be expected, in many cases individual states deviated greatly from the model. To control for such influences, a series of state dummy variables were added to the equations.** The state dummys for each regression model are reported in the Appendix.

Results

The regression results for all variables appear in Table 1. Because our concern is with the impact of abortion funding and family planning expenditures, we have not interpreted the coefficients for the control variables. These coefficients are usually statistically significant and in the direction predicted by previous research.

Abortion Rates

The model predicts state abortion rates fairly well ($R^2 = .89$). Both policy impacts are as predicted: A $1 per capita increase in family planning expenditures is associated with 1.046 fewer abortions per 1000 women, consistent with the notion that effective family planning policies reduce the need for subsequent abortions. Similarly, for each additional abortion funded by a state, the number of abortions increases by 0.42.

Maternal and Child Health Indicators

The remainder of Table 1 reveals a generally good level of prediction for the child and maternal health indicators ($R^2 > .69$). There is no relationship between family planning funding and teen

*The Alan Guttmacher Institute data on funded abortions and family planning are available for 1982, 1984, 1985, and 1987. Data were extrapolated for the missing years. That is, 1986 data were the average of the 1985 and 1987 data. The 1988 data were the weighted average of 1987 and 1990 data, weighting 1987 data twice as much as 1990 data.

**The dummy variables, as expected, improve the fit of the regression line and reduce the autocorrelation. Their inclusion has little impact on the substantive interpretation of either family planning or abortion funding. The apparent impact is to reduce the size of these coefficients; the result is a conservative estimate of impact compared with the ordinary least squares estimates. For low birthweights, specific time-point dummys were also included for 1987 and 1988 to correct for time-dependence problems.

TABLE 1—The Impact of Policy on Abortions, Teen Birthrates, Low Birthweights, and Premature Births: Pooled Estimates

Independent Variables	Dependent Variables						
	Abortion Rate	Teenage Birthrate	Low Birthweight	Premature Births	Late Prenatal Care	Infant Mortality	Neonatal Mortality
Family planning funding per capita	−1.046	−.026	−0.49	.045	−.261	−.159	−.134
	(5.47)	(.11)	(2.02)	(1.03)	(1.88)	(2.29)	(2.29)
Rate of publically funded abortions	.420	−.673	−.024	−.027	−.263	−.011	.003
	(4.76)	(7.81)	(2.73)	(2.83)	(7.56)	(.70)	(.25)
Percentage Black population	.110	.385	.105	.175	.069	.138	.130
	(3.44)	(10.87)	(35.00)	(39.08)	(3.85)	(21.33)	(24.34)

Notes. Coefficients are unstandardized regression coefficients; *t* scores are listed in parentheses. See the Appendix for fixed effects controls.

TABLE 2—National[a] Totals for Abortion Funding 1982 through 1988: Their Impact on Total Abortions and Birth Status

Indicator	States That Fund	States That Do Not Fund
Number of abortions	+563 866	−503 778
Births to teenage mothers	−151 907	+136 499
Low-birthweight births	−21 255	+18 453
Premature births	−23 928	+20 760
Late or no prenatal care	−232 570	+201 907

[a]Does not include the District of Columbia.

birthrates or premature births, but family planning funding is related to all other indicators. All other things being equal, each additional family planning dollar spent per capita by a state is associated with 0.049 percentage points fewer low-birthweight babies, 0.261 percentage points fewer births with late prenatal care, and 0.159 fewer infant deaths and 0.134 fewer neonatal deaths per 1000 live births. Funding abortions, in turn, has somewhat different impacts. All other things being equal, an increase of one funded abortion per 1000 women of childbearing age is associated with 0.673 fewer teen births per 1000 teenage women, 0.024 percentage points fewer low-birthweight babies,* 0.027 percentage points fewer premature births, and 0.263 percentage points fewer births with late or no prenatal care.

Two comments about the size of these coefficients are in order. First, funded abortions are associated with a major drop in births to teen mothers—perhaps as many as 0.67 teen births for every abortion funded. Second, many other impacts of abortion funding or family planning appear modest; however, even small changes in these variables can have a major impact.

The equations generated in Table 1 were used to estimate the impact of abortion funding and family planning expenditures in each state. To estimate the impact of abortion funding policies in states that fund abortions, the regression coefficients in Table 1 were multiplied by the actual funded abortion rate. The results were then translated from rates per 1000 women, or percentages, to actual numbers. For states that did not fund abortions, an estimate was made of what would have happened if the state *had* funded abortions. With all other state-level factors remaining the same, the mean funded abortion rate for states that actually funded abortions (4.97 per 1000 women) was used for these states. These numbers suggest the impact of not funding abortions. (The ecological analysis presented here cannot rule out the possibility that other factors caused these changes, but any such changes would have to be collinear with either funded abortions or family planning expenditures.)

Table 2 shows the national estimates. In states that funded abortions for one or more of the 7 years under analysis, there were an additional 563 900 abortions, 151 900 fewer births to teen mothers, 21 300 fewer low-birthweight babies, 23 900 fewer premature births, and 232 600 fewer births with late or no prenatal care. States that did not fund abortions had 503 800 fewer abortions, 136 500 more births to teen mothers, 18 500 more low-birthweight babies, 20 800 more premature births, and 201 900 more births

*This finding contradicts Currie et al.,[8] who find no impact. Their model used individual-level data and estimated models using least squares dummy variables. The inclusion of regional and year dummy variables might have eliminated the impact of state laws since states that fund abortions do cluster in some regions. A more precise measure of abortion funding is used here.

with late or no prenatal care. The cumulative impact of funding or not funding abortions for Medicaid-eligible women over this time period, therefore, could be substantial.

Table 3 estimates the impact of 1982–1988 family planning funding on abortions, low birthweights, late prenatal care, infant deaths, and neonatal deaths. These estimates were generated using the actual amount spent per capita in each state, and the predicted rates were then transformed into raw numbers. The total for abortions prevented, 670 000, suggests that an absence of family planning funding would likely have increased the number of abortions by about 6% nationwide. Family planning funds are also associated with 20 000 fewer low-birthweight babies and 106 900 fewer births with late or no prenatal care. These two impacts probably explain family planning's impact on infant and neonatal mortality; family planning funding was associated with 6500 fewer infant deaths and 5500 fewer neonatal deaths. Although these numbers are dwarfed by the national totals for neonatal and infant deaths, they represent a significant spillover benefit, given that family planning is directly targeted at unwanted pregnancies rather than at infant mortality.

Conclusion

Our analysis links public funding for abortion to public health benefits. States that fund abortions have substantially fewer teen births and about one-fourth fewer cases of inadequate prenatal care. Because maternal age of less than 20 years and inadequate prenatal care[29] are both risk factors for premature and low-birthweight infants,[30] it is not surprising that abortion funding is associated with a modest reduction in each of these birth outcomes.

Publicly subsidized family planning services also produce public health benefits, although the dynamics are different. Family planning funding is associated with fewer low-birthweight babies and fewer births with late or no prenatal care, and these impacts reduce neonatal and infant mortality. In contrast to abortion funding, however, family planning expenditures show almost no effect on teenage birthrates. Therefore, even though both abortion and family planning address unwanted fertility, their respective public health outcomes are distinctly different. These outcomes can be attributed to differences in clientele, delivery systems, and funding mechanisms.

Clientele

Patient characteristics may explain differences in maternal and child health outcomes. Women who have abortions are predominantly young, single, and of modest means[31]; more than half are nulliparous and have not experienced prior induced abortions.[21] Many family planning patients are also young, single, and of low income.[32] With the cutbacks in public funds for family planning during the 1980s, however, family planning clinics focused on serving existing patients. For the most part, there was no outreach to new patients and teenagers.[33] Therefore, we believe that fewer teens were served during the past decade than in previous periods. We would also surmise that a greater proportion of family planning patients have experienced a live birth or pregnancy.

Delivery Systems

Family planning services are more geographically accessible than abortion services. Publicly subsidized family planning services are delivered through provider agencies operating at 5460 sites,[34] while 90% of abortions are provided in only 1542 nonhospital facilities.[11,35] Family planning services are offered in nearly every county in the United States; on the other hand, 51% of metropolitan and 93% of nonmetropolitan counties lack an abortion provider.[11]

Family planning clinics also provide more continuous care than do most abortion providers. When a woman receives services at a family planning clinic, she is expected to be a continuing patient. Moreover, a family planning patient has entered a health care delivery system where she will be provided with or referred to other maternal and child health services as needed. In contrast, a woman who receives an abortion is far more likely to get only a single health service. This is because most abortions are performed in clinics where abortion is the main service provided,[33] and referral patterns are unlikely to be as well established as they are in a family planning clinic. An abortion patient is also more likely to live in another county or state, which also decreases the likelihood of a successful referral to another health care provider.

TABLE 3—National Totals for Benefits from Family Planning

Indicator	50-State Total
Decline in low-birthweight births	20 025
Decline in late prenatal care	106 867
Decline in infant deaths	6 498
Decline in neonate deaths	5 476
Decline in number of abortions	670 384

Funding Mechanisms

A third difference between abortion and family planning services is how they are financed. The 12 states that fund abortions do so through state Medicaid programs, a fee-for-service funding mechanism whereby patients go to a health care provider for a single service. In contrast, even though Medicaid is now the largest single contributor to the national family planning effort, most family planning providers receive funds from a variety of public sources.[19] If the family planning agency receives *any* Title X funds, it must provide an array of services including appropriate referrals for other health services.

The difference in the public health outcomes of abortion and family planning services presents a strong argument for a more integrated approach to the delivery of both services. The fact that so many young women initiate family planning *after* an unwanted pregnancy certainly calls for a greater and more effective family planning effort. Given the current realities of service delivery and funding, the projected outcomes in Tables 2 and 3 provide reasonable data for policy deliberations concerning family planning and abortion funding.

States seldom make policy on abortion funding based on public health benefits. The recent congressional debate on abortion funding indicates that this holds true for the federal government as well. However, we hope that this information will at least contribute to the debate when it inevitably recurs. □

APPENDIX—Fixed Effects Estimated for the Following States in the Equations Listed in Table 1

Abortion rate: Arkansas, Connecticut, Delaware, Florida, Georgia, Idaho, Indiana, Kentucky, Maine, Maryland, Massachusetts, Mississippi, Nevada, New Mexico, North Carolina, Rhode Island, South Carolina, South Dakota, Utah, West Virginia, Wyoming.

Teen birthrates: Colorado, Iowa, Kentucky, Louisiana, Maryland, Minnesota, Mississippi, New York, Oklahoma, Rhode Island, Utah, Virginia, Washington.

Low birthweights: Alaska, Colorado, Hawaii, Nevada, Washington, Wyoming.

Premature births: Connecticut, Hawaii, Kentucky, Maryland, Minnesota, Rhode Island, Washington, West Virginia, Wyoming.

Late prenatal care: Arkansas, Iowa, Minnesota, New Mexico, New York, Oklahoma, South Carolina, South Dakota, Utah, Virginia, West Virginia.

Infant mortality: Alaska, Arkansas, Illinois, Louisiana, South Dakota, Wyoming.

Neonatal mortality: Alabama, Arkansas, Delaware, Illinois, Louisiana, Mississippi, New Hampshire, Washington.

The Costs and Financing of Perinatal Care in the United States

ABSTRACT

Objectives. The purpose of this study was to estimate the aggregate annual costs of maternal and infant health care and to describe the flow of funds that finance that care.

Methods. Estimates of costs and financing based on household and provider surveys, third-party claims data, and hospital discharge data were combined into a single, best estimate.

Results. The total cost of perinatal care in 1989 was $27.8 billion, or $6850 per mother–infant pair. Payments made directly by patients or third parties for this care totaled $25.4 billion, or about 7% of personal health care spending by the nonaged population. Payments were less than costs because they did not include a value for direct delivery care or for bad debt and charity care, which accounted for $2.4 billion. Private insurance accounted for about 63% of total payments, and Medicaid accounted for 17% of the total.

Conclusions. National health reform would provide windfall receipts to hospitals, which would receive payment for the considerable bad debt and charity care they provide. Reform might also provide short-term gains to providers as private payment rates are substituted for those of Medicaid. (*Am J Public Health.* 1994;84:1473–1478)

Stephen H. Long, PhD, M. Susan Marquis, PhD, and Ellen R. Harrison, MA

Introduction

The financing, delivery, and medical effectiveness of perinatal care in the United States has been a subject of continuing concern for decades. Most obvious among the causes of concern are the poor relative position of the US infant mortality rate among those of other nations and the persistent disparity in infant mortality rates between Blacks and Whites in this country.[1,2] A number of distinguished commissions and panels have studied the problem,[3–5] and major restructuring of the delivery system has been implemented.[6] Recently, significant expansions of eligibility for Medicaid financed care have been made for pregnant women and infants.[7] The prospect of national health reform heralds future changes in spending and financing for maternal and infant health care services.

One dimension that needs to be monitored as the nation continues to wrestle with this problem is the financing of perinatal care. That is, how much do we spend? For what services? Who pays the bills? How will reforms alter the mix? Several previous studies have attempted to answer one or more of these questions.

Since the 1970s, the Health Insurance Association of America has produced periodic estimates of typical charges for inpatient hospital care and fees for physician services associated with a normal delivery and a cesarean section.[8,9] Weighting the association's most recent (1989) estimates of the typical charge for each procedure by their respective frequencies, the per capita charges for the specified maternity care services were about $5050.

Fuchs and Perreault provided the first estimates of aggregate expenditures on reproduction-related health care—including obstetrical care, infant care, contraception, abortion, and infertility services—in the United States.[10] Aggregate obstetrical spending was based on the Health Insurance Association of America estimates of per capita charges for hospital and physician services multiplied by the total number of births, supplemented by estimates of additional tests not accounted for in the association's service bundle. Spending on infant care was estimated from Health Insurance Association of America charge data on nursery care for newborns and estimates of the use and charges for neonatal intensive care, well baby care, and other services. Inflating the Fuchs and Perreault estimates for 1982 to 1989 dollars—using the medical care component of the Consumer Price Index—and births, aggregate spending for obstetrical and infant care would be $14.5 billion and $11.5 billion, respectively.

A series of reports by staff of the Alan Guttmacher Institute assembled estimates of charges for perinatal care and provided considerable information about the major sources of third-party financing for such care.[11–14] For inpatient hospital charges, the authors used either the above Health Insurance Association of America survey or a survey conducted by the Commission for Professional Hospital Activities. Physician charges were also taken from the Health Insurance Association of America. Multiplying these estimated charges by the number of births, the institute's 1985 estimate of total charges for maternity care was $23 billion, given 1989 dollars and births.

Editor's Note. See related editorial by McCormick and Lee (p 1376) in this issue.

Recently, Lewit and Monheit updated the Fuchs and Perreault estimates of the average cost and aggregate cost of US maternity and infant care.[15] Again, they relied on the Health Insurance Association of America estimates of hospital and physician charges to value prenatal, delivery, and routine newborn care. For infant care, they used recent data from the 1987 National Medical Expenditure Survey (NMES). Aggregate expenditures on perinatal care in 1987, adjusted to 1989 dollars and births, were $34 billion according to this source.

The purpose of the present study was to build and improve on this earlier literature in several ways. First, previous work has used charges as the measure of valuing services. Since few third-party payers actually pay full charges, and because maternity care is a well-documented source of bad debt and charity care, we introduce the concepts of payment and cost as alternative measures of value. Second, earlier studies often have depended on surveys to measure charges for the "typical" or "modal" service bundle. Aggregate totals produced from such estimates are at risk of considerable error, should either the quantity of use or the charge for the modal service mix differ from their averages. To measure aggregate spending more accurately, we used administrative records for episodes of care whenever possible to measure the "mean" charge, thereby accounting for outliers, whether they be low users of prenatal care or extremely high-cost hospitalizations. Third, we attempted to disaggregate services into discrete episodes of care for mothers and infants somewhat more extensively than has been done in the past. Fourth, we examined the distribution of spending by source of payment as well as by type of spending; except for the Alan Guttmacher Institute study, previous studies have looked only at the distribution by service type. Finally, we greatly expanded the number of sources used to make the estimates, contributing, we hope, to their accuracy.

Here we measure costs and financing of maternal and infant care in 1989. We chose that year because it preceded most of the recent Medicaid eligibility expansions and provided a baseline against which those expansions and other reforms could be monitored. We conclude with a discussion of the implications of Medicaid reforms and national health reforms for the mix of spending and financing observed in 1989.

Methods

The Flow of Funds Matrix Framework

The structure that we used to measure the financing of maternal and infant health care in the United States was modeled after the National Health Expenditures Accounts, a continuing series currently maintained by the Health Care Financing Administration to describe the flow of funds financing all health care in the United States.[16] The flow of funds matrix is a way of describing activities; it allowed us to know the magnitude of the current system expressed in the common metric of dollars.

The columns of our flow of funds matrix categorize expenditures by type of service, and the rows categorize expenditures by payer. The services that we measured included maternity care from conception until 60 days after delivery and infant care through the first year of life. Although the term "perinatal care," in its technical usage, would not include all of the infant care we measured, we use "perinatal" as a shorthand in this article to refer to all of these maternal and infant services. The service categories classify this care by the stage of the process: prenatal and postdelivery care, delivery services (those provided to the mother at delivery), newborn care (services provided to the newborn from birth to the initial hospital discharge), and infant care (care delivered from hospital discharge through the first year of life). These categories are further classified by provider (inpatient hospital services and services of physicians and other health care providers).

The rows of the matrix categorize expenditures by payer. Some of the care is covered by private third-party payers and some by Medicaid and other government insurance programs. The latter category includes CHAMPUS (the Civilian Health and Medical Program of the Uniformed Services), other care paid for by the Department of Defense, and other state and federal programs that make payments on behalf of a patient receiving care. Self-pay includes patient payments made by uninsured patients; for insured patients, it includes their payments for cost sharing and services not covered by their plans. The final category is direct delivery care, within which we include all care provided to a patient without payment on behalf of that particular patient. This includes care financed by government grants and contracts, such as first provided by community and migrant health centers, Title V clinics, and Crippled Children's Services, as well as bad debt and charity care from physicians and hospitals.

Measurement Concepts

It was noted above that, when estimating expenditures, all earlier studies have valued the resources devoted to perinatal care according to the charges of hospitals and the prevailing fees charged by physicians. Increasingly over the last decade, third-party payers have either refused to pay full charges, as has Medicaid, or negotiated discounts, as have Blue Cross and Blue Shield and most managed care organizations. Moreover, uninsured patients are frequently unable to pay much, if any, of a hospital's normal charge for delivery, but generally they are not denied care. Therefore, using charges to estimate direct expenditures almost surely results in an overestimate.

Instead of charges, we used two alternative measures to value perinatal care resources. First, we estimated direct payments for care by patients and on account of patients by third-party payers. In other words, we attempted to measure what was actually collected by the provider for the care of a particular patient. This concept does not include contributions that are not tied to particular patients, such as federal block grants to states for Title V programs and general contributions by local governments to public hospitals for charity care. Second, we estimated the cost of care provided to patients. In the case of hospital services, this is the value of the resources the hospital assembles to provide care, including wages and salaries, supplies, utilities, and depreciation on plant and equipment. In the case of physician services, this represents practice costs plus the monetary return physicians accept to see their patients, whether paying full fees or not.

The payment may be either greater or less than the cost. For example, private insurers pay most or all of the provider's charge, which generally exceeds the average cost of providing the service. On the other hand, our payment concept attaches no dollar value to government direct delivery services or charity care to a patient because no direct payment for the patient's care is involved. In contrast, our cost concept places the same positive cost value on a unit of care delivered in a public health clinic or on a unit of charity care as it does on a unit of care for which the full charge was paid.

Data and Estimation Methods

Overview. Our estimates of aggregate payments or costs for each cell of the matrix were based on a variety of different data sources, including household and provider surveys, third-party claims data, hospital discharge data, and the published literature. From these sources, we estimated the average charge per delivery or per infant for each of our service categories (the column totals) and multiplied these per case estimates by data from the vital statistics system on the number of births and fetal and infant deaths to arrive at the aggregate service totals. We allocated the aggregate service totals to payer using estimates of the distribution of charges for each of the service categories (or columns) by payer from our data sources. We converted the resulting matrix of charges to payments and costs using estimates of the ratio of payments to charges for different payers and of costs to charges.

Data availability dictated the estimation strategy that we adopted. There was no data source that allowed us to directly estimate any cell in our payment or cost matrix and only one data source that permitted us to estimate charges categorized by both type of services and type of payer for all maternal and infant spending. Some data sources provide information only about spending in one setting (e.g., inpatient care) or for selected stages of care (e.g., delivery services). Other sources provide estimates of total spending but do not categorize it by type of service or payer. The single source that provides information about charges by type of service and payer is a sample survey, and some cell estimates derived from this database are subject to respondent reporting error and are unreliable because of very small sample size. As a result, we have pooled a number of data sources to estimate our matrix.

Data on charges per case. The data sources included in our estimate of charges per case were NMES, a 1987 survey of about 14 000 US households; 1990 insurance claims data for patients covered by the Aetna Insurance Company; 1989 data from the MEDSTAT data system representing the health care use experience of more than half a million workers enrolled in one of 32 different group health insurance plans in all areas of the country; the Health Insurance Experiment, a controlled trial in health care financing that collected health insurance claims data from almost 6000 individuals in six sites throughout the country for a 3- or 5-year period[17]; 3 years of insurance claims data for employees and dependents of three large employers in two states; Medicaid claims data from four states[18–20]; the California Office of Statewide Health Planning and Development 1988 Annual Discharge Abstracts, which contain a record for each discharge from a California hospital in the year; data from the Hospital Cost and Utilization Project, a source of hospital discharge abstracts from a national sample of hospitals; and published estimates from the Health Insurance Association of America[9] and the Alan Guttmacher Institute.[13]

Our data sources came from different years and, in some cases, from limited geographic areas. We adjusted all dollar estimates to 1989 dollars using the hospital or physician services component of the Consumer Price Index. We adjusted per case expenditure estimates based on data from a single state to national prices using the Medicare Geographic Practice Cost Index.

We averaged the estimates of per case charges from the various databases to obtain a best estimate. Because we gave equal weight to each database in computing our estimate without regard to the payer group represented (e.g., patients covered by private payers vs Medicaid patients), we adopted the assumption that average patient needs and the average service mix do not vary by payer status. Although this may impart some bias, the direction is not clear. For example, Howell et al.[19] found that women on Medicaid tend to initiate prenatal care later in the pregnancy and are less likely to have a cesarean section delivery, both of which would lead to lower charges. In contrast, women on Medicaid have poorer birth outcomes than non-Medicaid women, probably leading to higher charges for infant care.

We had more confidence in estimates from the databases of the average total charge for maternity care and newborn care at delivery than for the allocation between prenatal care, care for the mother at delivery, and newborn care because of differences across payers and providers in billing practices. For example, some physicians submit global bills for all maternity care, whereas some submit separate bills for each service. Some hospitals have a single bill for both the newborn and the mother, whereas others submit separate bills. Moreover, there is less variability among studies in the estimate of average total charges than in estimates by type of service. We also had more information about total charges for the mother and newborn or charges during the first year of life than we had about the components, because some databases do not provide the information to allocate charges by type of provider or type of service. Therefore, we first estimated per case total charges for the mother and newborn at delivery and per case total charges for the first year of life by averaging the estimates from our various data sources. Then we distributed these charges among service and provider categories using the average share of the total attributable to the category estimated from the different databases. The service-specific per case charge estimates were multiplied by data on the number of cases from the vital statistics system to produce aggregate charge estimates. An appendix, available on request from the authors, provides more detail about the estimation and summarizes the data used to construct the charge matrix. This appendix also reports some sensitivity analyses that show our estimates vary by only about 10% when we alter some key assumptions, and it presents some independent aggregate estimates where available for specific payer and service categories that validate our constructed estimates.

Distributing charges among payers. Aggregate charges were distributed among the payers by using estimates of the service-specific share of the total attributable to the payer. Estimates of the payer share came from the following databases: the California Hospital Discharge database; the Hospital Cost and Utilization Project database; NMES; the National Hospital Discharge Survey, a sample of discharge records from about 400 hospitals nationwide; the 1988 National Maternal and Infant Health Survey, a retrospective history of the use patterns of more than 18 000 pregnant women; and the National Ambulatory Medical Care Survey, a sample of patient records from a nationwide sample of physicians. The data used in constructing payer shares are also available from the authors by requesting the appendix.

Calculating payments and costs from charges. Aggregate inpatient hospital charges for each payer were adjusted to reflect payments by means of payment-to-charge ratios by payer category derived from data from the American Hospital Association,[21] the Hospital Cost and Utilization Project (for private and public third parties), and a large private insurer (for private third parties). The payment-to-charge ratio is always less than one,

reflecting deductions from gross charges for contractual adjustments (or "discounts") and uncompensated care for the pool of patients having the same primary payer type. For physician services, we based our estimates of payment-to-charge ratios on data from the American Medical Association's (AMA) Socioeconomic Monitoring System, which is an ongoing survey of nearly 3000 physicians.[22,23] Specifically, we calculated these ratios on the basis of data on discounts from the usual fee for established patient office visits by payer and specialty-specific data on charity care provided, as a percentage of practice time, for obstetrics/gynecology, general/family practice, and pediatrics. For private third-party payers, we averaged the AMA estimate of the payment-to-charge ratio with one obtained from a large private insurer.

Hospital costs were estimated on the basis of an overall hospital cost-to-charge ratio from the Hospital Cost and Utilization Project; that is, we implicitly assumed that costs per patient did not vary by payer type. Our estimate of the cost-to-charge ratio for physician services was the ratio of our estimate of aggregate payments to aggregate charges net of charges for direct delivery care. In effect, it was a cost-to-charge ratio based on the observation that, after covering office expenses, this was the compensation for which private practice physicians were willing to work to provide this total bundle of services, whether paid or not. Costs for each cell were calculated by multiplying charges by the cost-to-charge ratio. This same ratio was applied to our estimate of charges for direct delivery care.

Results

Payments for Maternity and Infant Care in 1989

Payments for maternity and infant care were estimated to be $25.4 billion, or about $6250 per mother–infant pair, in 1989 (Table 1). These payments included those made directly by patients to providers or made by a third party on behalf of a patient; they did not include a value for direct delivery care or bad debt and charity care. Such payments represented about 4.5% of personal health care spending by all Americans and about 7% of health care spending by the nonelderly population.

About 15% of total payments were for prenatal and postdelivery services ($910 per mother), 48% were for obstetric delivery services ($3020 per mother), 17% were for newborn care ($1040 per newborn), and 20% were payments for care received during the first year of life ($1280 per infant).

Payments to hospitals accounted for 56% of the total, and payments to physicians and other providers accounted for 44%. Hospital payments on behalf of the mother totaled $9 billion and physician payments $7 billion. Hospital payments for newborns and infants during the first year of life were $5.3 billion, and

payments of other providers totaled $4.1 billion.

Private insurance paid about 63% of the total; Medicaid, 17%; other government insurance programs, 7%; and out-of-pocket payments by patients, 14%. The Medicaid share, which totaled $4.2 billion, represented 7% of Medicaid outlays in 1989.

Private insurance paid a smaller fraction of infant care than of maternity and newborn care (52% vs 67%) with out-of-pocket payments picking up a larger fraction of the infant care (21% vs 11%). Medicaid accounted for a somewhat smaller fraction of physician payments than of hospital payments (10% vs 21%) because Medicaid discounts relative to private payer discounts were greater for physician than for hospital services.

Costs of Maternity and Infant Care in 1989

The total cost of maternity and infant health care in 1989 was $27.8 billion, or $6850 per mother–infant pair (Table 2). This exceeded payments made directly on behalf of patients by $2.4 billion, which represented uncompensated care and the direct delivery of maternal and infant health services.

The cost of services covered by private payers was less than the payments actually made by these third parties; payments exceeded costs by almost $2 billion, or 13%. This was due in part to cost shifting by providers to private payers to collect for charity care and for care to Medicaid patients that, on average, was reimbursed at less than cost. As a result, the cost of services covered by public insurance programs or paid for directly by the patient exceeded the payments made for these services. For example, Medicaid paid $4.2 billion for perinatal care services, whereas we estimated the cost of these services to be $5.6 billion.

The value of uncompensated hospital care and hospital care provided through direct delivery programs was $1.6 billion, or 10% of the total cost of hospital services for maternity and infant care. For physician services, the value of direct delivery services and other uncompensated services amounted to $0.8 billion, or 7% of the total cost of physician services for pregnant women and infants.

Discussion

How is the level of perinatal care financing and its pattern by payer and by

service that we measured for 1989 likely to change in the future? Many trends will affect the level and pattern of financing, including technological changes in the treatment of high-cost infants and changing practice patterns, such as shorter inpatient hospital stays for normal deliveries. Although we cannot comment on all important trends here, we offer some thoughts about the effects of two forces: the recent Medicaid eligibility expansions for pregnant women and infants and the prospect of national health reform resulting in universal health insurance coverage for all Americans.

The share of infants covered by Medicaid increased substantially between 1989 and 1992 during the phasing in of the Medicaid eligibility expansion, from 22% to 31%, or 9 percentage points (based on our tabulations of the Current Population Survey). What is the implication for provider payments? If the newly eligible were formerly uninsured, then providers should be experiencing some revenue gains, since the costs of treating these women and newborns are not likely to have changed. But the proportion of uninsured infants fell by only 2 percentage points, from 14% to 12%. Nearly all of the remainder of the shift among payers came through a 6 percentage point reduction in private insurance coverage. If these estimates prove accurate, and given the relative payment rates of Medicaid and private insurance, expanding Medicaid into higher ranges of the income distribution may not deliver the effect on the bottom line once envisioned by some provider groups.

The effect of national health reform on the quantity and pattern of current financing of perinatal care would depend on several factors, including the minimum benefit package (if any), changes in payment rates by payers, and behavioral changes by providers and by patients. The use of inpatient hospital services for delivery and newborn care seems unlikely to change much in response to health reform. Although these services would surely be included in any minimum benefit package, the uninsured tend to receive care in the current system despite their inability to pay for it. An increase in use of prenatal and well baby care under universal insurance seems more likely, should they be included in a basic benefit package. The different education and income levels of the uninsured relative to those of the insured make the magnitude of the increase quite uncertain, however.

In contrast, the effects on the pattern of financing would be substantial. Universal insurance might provide substantial windfall receipts to hospitals, at least in the short run. At minimum, they would receive payment for nearly all of the considerable bad debt and charity care they now provide. In addition, many health reform plans would replace Medicaid acute care with government-subsidized private insurance. As we observed earlier, private payments now exceed the cost of services provided to patients, in part reflecting shifting costs of public patients whose care is reimbursed below cost. Thus, as private payment rates are substituted for those of Medicaid, hospitals will almost surely realize windfall profits.

The ultimate financial outcome, however, would depend on the net effect of changes in payments from various of their other payers. For example, under managed competition plans these short-term windfalls might be given away by hospitals over the longer run in the form of discounts to cost-conscious health plans. Alternatively, under a more regulated model, the government might take them back, either by regulating lower payments from other payers or by imposing a hospital excise tax. The implication of such changes is that our two measures of value, payments and costs, are likely to come much closer to resembling one another, and the current variation in payment-to-cost ratios by payer type is likely to be reduced or eliminated. Under some reform models, this is a tautology, since they would either greatly reduce the number of payers or reduce their freedom to use their own payment amounts.

Aside from the possibility of larger increases in the demand for their services under national health reform, the implications of payment changes for physicians are similar to those for hospitals. Whatever bad debt and charity care they would otherwise provide would become paid care if everyone were insured for their services, aside from any cost sharing in the plan. And Medicaid might become better paid. But physicians' ability to sustain the windfall over the long run would depend on the decisions of other payers, government regulation and taxation, and the competitive behavior of their colleagues. □

Targeting Cancer Control: The State Cancer Control Map and Data Program

Forrest A. Pommerenke, MD, Robert W. Miller, MD, DrPH, Sudhir Srivastava, PhD, and Susan P. Ackermann, PhD

ABSTRACT

The State Cancer Control Map and Data Program (National Technical Information Service, Springfield, Va) allows state and county mortality maps and data tables to be tailored according to the user's choice of cancer site, age, gender, race, county, and time period between 1953 and 1987. Counties and subpopulations within these maps and data tables that are identified as having exceptionally high rates of specific cancers can then be targeted for early detection or primary prevention. These maps and data tables provide a means for focusing state, local, and individual efforts to reduce cancer mortality in appropriate populations in areas with high mortality rates. (*Am J Public Health.* 1994;84:1479–1482)

Introduction

A substantial reduction in cancer mortality can come from improvements in early detection by primary care physicians and from efforts to decrease socioeconomic, environmental, and behavioral risk factors, especially tobacco use.[1,2] Cancer control should apply to all persons but especially to populations who by age, gender, and race are at high risk for type-specific cancers.[3]

Practicing physicians and community health officials may be at a loss as to where and how to begin cancer control programs. One starting place is the examination of local cancer mortality patterns.[4] The first *Atlas of Cancer Mortality,* developed in the United States by Fraumeni and his associates, provided a panoramic view of variations in cancer mortality by county.[5] It was immensely useful for studies of etiology[6] and was followed by two atlases of cancer mortality among US non-Whites[7,8] and another of cancer mortality among Whites[9] by aggregates of counties known as State Economic Areas. The State Cancer Control Map and Data Program (hereafter called the Map Program) described here, a variation on the previous theme, provides cancer mortality statistics from 1953 to 1987 and allows maps and detailed tables to be tailor-made according to the interest of the user.

Methods

To encourage early cancer detection and prevention activities at the local level, the Map Program was developed by the National Cancer Institute with supplemental support from the Centers for Disease Control and Prevention and the American Cancer Society. This software program provides state and county mortality statistics in sufficient detail to allow physicians and health officials to analyze local patterns using mortality data from the National Center for Health Statistics and population data from the US Census Bureau.

After the user selects the state, type of cancer, and population parameters from the main menus, the county mortality rates are calculated, age adjusted, and tested for significance. Age-specific comparisons can also be made for each 5-year age group. Each county is color coded to show its mortality rate relative to the national rate for the same population parameters and period. Counties colored dark red have rates that are significantly higher than the national rate ($P < .05$) and 33% or more above it. Counties shown in light red have lower rates, but these rates are still significantly above the national average ($P < .05$). Yellow is for counties with rates similar to the national average, and green is for counties with rates significantly below the national average ($P < .05$). Once the map is created on the screen, a summary table can be printed that lists the counties

At the time of the study, Forrest A. Pommerenke was with the Early Detection Branch, National Cancer Institute, Bethesda, Md; he is now with the Department of Preventive Medicine, Medical College of Wisconsin, Milwaukee. Sudhir Srivastava is with the Early Detection Branch, and Robert W. Miller is with the Epidemiology Branch, National Cancer Institute. Susan P. Ackermann is with the Division of Cancer Prevention and Control, Centers for Disease Control and Prevention, Atlanta, Ga.

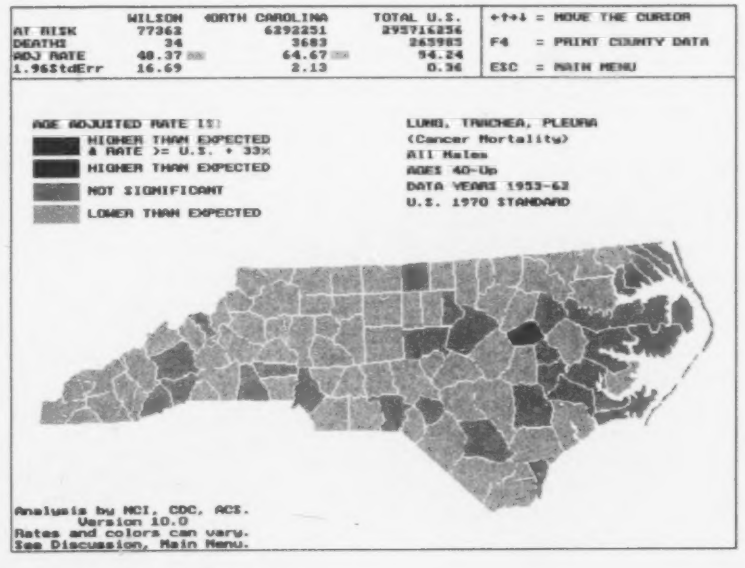
Note. In this example, the parameters are entered for the map shown in Figure 2.

FIGURE 1—Main menu, State Cancer Control Map and Data Program.



Note. Cursor is in Wilson County.

FIGURE 2—Lung cancer mortality in North Carolina in all males aged 40 and older, 1953 through 1962.

according to the rates or number of deaths.

The user can then move the computer cursor to highlight a specific county on the screen. A display above the state map will appear, showing the number of deaths in the county, state, and nation, along with their age-adjusted rates and 95% confidence intervals. Once the cursor is within a county, a summary table can be printed that provides the number of deaths and age-specific rates for each age group for each 5-year period and the age-adjusted rates for the county.

Results

In the example in Figure 1, the highlighted items create a map showing the county mortality rates in North Carolina for all males 40 or more years of age who died of lung cancer from 1953 through 1962. The county rates were relatively low during this period; thus, the map appears predominantly green on the computer screen and light gray in Figure 2. This is in contrast to the much higher rates shown in the map for a more recent period (1978 through 1987), which appears predominantly yellow and red on the screen and as the medium to darker grays in Figure 3. In both figures the cursor has been placed in Wilson County, the data for which are shown at the top of the screen.

Encouraging Smoking Cessation

The county tables (not shown) printed from the Map Program summarize state and county data and can reveal trends in mortality. For example, the county summary table created for Wilson County, North Carolina (described earlier), shows a rise in lung cancer mortality from an age-adjusted rate of 48 per 100 000 in 1953 through 1962 to 283 per 100 000 in 1978 through 1987: a sixfold increase. The printed tables show that the greatest concentration of deaths is in men 55–74 years of age, but there is substantial mortality in younger men. The rate in the most recent interval was well above the US national rate of 199.73 during the same period (table, top of Figure 3).

The maps presented in Figures 2 and 3 could be used by public health officials to emphasize the importance of smoking cessation. Statistics taken from the Map Program tables showing ever-increasing mortality from lung cancer could provide a stimulus to local officials to restrict tobacco use in public places and to control youth access to tobacco.[10]

Increasing Cervical Screening of High-Risk Women

Figure 4 shows several Florida counties from 1968 through 1987, with cervical cancer mortality rates in non-White women that are three to five times higher

than those for White women. If the rates for non-Whites were reduced to those for Whites, the number of deaths due to cervical cancer among non-Whites in Duval–Jacksonville County, for example, would be reduced from 169 (table, top of Figure 4) to about 65. Data such as these can help focus attention on high-risk women who could benefit from increased cervical cancer screening.[11]

Implementing New Screening Procedures

The *ras* oncogene, recently found in stool specimens from patients with curable colon cancer,[12] is one of a number of promising biomarkers that may find use in early detection.[13] When these markers are ready to be tested or used in screening high-risk groups, the Map Program can help determine where they might best be used: i.e., in a high-mortality-rate county among persons with the highest age-, sex-, and race-specific mortality rates. In regard to colorectal cancer, the Map Program reveals that one such location is Lackawanna County, Pennsylvania, where the colorectal mortality rate for all persons 40 or more years of age (83 per 100 000) was about 45% above the national average (57 per 100 000) from 1978 through 1987 (Figure 5).

Conclusions

The Map Program is easily used on personal computers. The versatility of the program is exemplified here by maps created according to parameters set by the user to show cancer mortality rates for several sites, by age group, for either sex, for Whites and/or non-Whites, and for different time intervals. Data from the program may also be used in correlation studies depending on the availability of other county-specific data bases. The program will be updated periodically.

Public health officials should be cautioned that rates may be higher or lower by chance, especially when the population at risk is very small. The data responsible for abnormal rates should be reviewed carefully before resources are committed to extensive evaluations or interventions.[14,15]

Persons living in areas with high mortality rates can be particularly advised to take advantage of effective early detection procedures and preventive measures. In the future, populations at high risk for certain cancers may benefit from the use of biomarkers for early detection, chemopreventive agents, and diets, all of which are under investigation. □

Elevated Blood Lead Levels among Construction Workers in the Massachusetts Occupational Lead Registry

Richard Rabin, MSPH, Daniel R. Brooks, MPH, and Letitia K. Davis, ScD

ABSTRACT

Although the construction industry until recently was exempt from the Occupational Health and Safety Administration General Industry Lead Standard, including its medical monitoring provisions, periodic blood lead tests have been required for residential "deleaders" and structural painters in Massachusetts. Sixty-three percent of the 381 registrants in the Massachusetts Occupational Lead Registry with blood lead levels of 1.93 μmol/L or higher are construction workers. This proportion is much higher than that reported by registries of several states selected for comparison. These data highlight the need for better protection from lead exposure and the effectiveness of mandatory medical surveillance in identifying elevated blood lead levels among construction workers. (*Am J Public Health.* 1994;84:1483–1485)

Introduction

Published reports of overexposure to lead among construction workers are numerous. These reports come from two sources: case studies of particular work sites or projects[1–4] and presentations of aggregate data from state occupational lead registries.[5–8] In the registry reports, construction workers constitute only a small proportion of total registrants, although they comprise a larger percentage of those with the highest blood lead levels. This low rate of detection[9] is thought to be due to a lack of regular blood lead monitoring, rather than a low incidence of elevated blood lead levels. On the federal level, the construction industry has been exempt, until recently, from the Occupational Safety and Health Administration's (OSHA) Lead Standard,[10] which has medical monitoring requirements, and there are few states with regulations requiring blood lead monitoring of construction workers. An interim OSHA lead standard for construction workers was promulgated in May 1993.

The Massachusetts Occupational Lead Registry was established in April 1991. Since that time it has been collecting information from clinical laboratories on elevated blood lead levels among Massachusetts workers. The regulatory environment for construction workers in Massachusetts is different from that in most other states, and this difference has an impact on the number of reports received of elevated blood lead levels among construction workers.

Under Massachusetts workplace regulations, a subgroup of construction workers—residential lead abatement workers ("deleaders") and workers who remove lead paint from structures—are required to have periodic blood lead tests. Deleaders must be tested every 2 to 3 months, and all results must be reported by laboratories analyzing blood lead to the Massachusetts Department of Labor and Industries.[11] The regulations requiring blood lead monitoring among structural painters are much less precise. Workers need only be tested at the start of a project and then "periodically."[12] In practice, these regulations have not been enforced for house painters and enforced only sporadically for bridge painters (personal knowledge of one of the authors [R. R.] who works in the Massachusetts Department of Labor and Industries).

Despite these limitations, the existence of regulations mandating blood lead monitoring in Massachusetts presents an important opportunity to examine lead exposures among the construction work force. In this study, we review data on blood lead levels among construction workers reported to the Massachusetts Lead Registry during its first 2 years of operation. We also compare findings from Massachusetts with those from other states.

Methods

Clinical laboratories in Massachusetts must report the results of all blood lead tests over 0.72 μmol/L (15 μg/dL) for adults aged 15 years or older to the Department of Labor and Industries, Division of Occupational Hygiene.[13] Individuals with blood lead levels of 1.93 μmol/L (40 μg/dL) or greater are contacted. The follow-up procedure includes a telephone interview in which questions are asked concerning source of exposure and participation in a blood lead testing program. The present analysis is based on data reported to the Registry between May 1991 and April 1993. Data are based

TABLE 1—Construction Workers as a Proportion of Total Registrants with Occupational Exposure in the Massachusetts Lead Registry and in Lead Registries in Selected States

	Massachusetts	California	Texas	New Jersey	New York	Maryland
Years of data reviewed[a]	2	3¾	1	3½	2	3
Total number of registrants with occupational exposure[b]	311	1503	177	1870	3071	592
Percentage of registrants in construction industry	63.0	2.1	5.6	4.8	4.3	48.6
Employed males in construction industry—annual average	79 443	613 701	368 256	175 281	341 906	148 968
Annual rate of registrants per 100 000 in construction industry	123.4	1.3	2.7	14.5	19.2	64.4

Note. Data in the table are based on blood lead levels of greater than or equal to 1.93 μmol/L for Massachusetts, California, and Texas; and greater than or equal to 1.21 μmol/L for New Jersey, New York, and Maryland.

[a]Refers to years of data available for analysis. Registries may have been in existence for longer periods of time. Data are from the following time periods: Massachusetts, May 1991 through April 1993; California, April 1987 through December 1990; Texas, January through December 1989; New Jersey, January 1986 through June 1989; New York, January 1987 through December 1988; Maryland, January 1988 through December 1990.

[b]Based on cases with industry information available.

on the highest blood lead test for each registrant.

For this analysis, registrants were categorized as deleaders, other construction workers (primarily house and bridge [structural] painters), and nonconstruction workers. These categories are based on literal descriptions of employers obtained from physicians or through the registrant interviews.

The proportion of persons in the Massachusetts Lead Registry who are construction workers was compared with the proportions in five other states' registries. The proportion of employed Massachusetts construction workers appearing as registrants in the lead registry was also compared with the proportions in those states.

Data for comparison with the Massachusetts Registry were available from the California, Maryland, New Jersey, New York, and Texas registries. Maryland has been one of the very few states with a comprehensive standard for exposure to lead among construction workers, including a requirement for blood lead monitoring.[14] The remaining states, including Massachusetts, have not had such a standard.

Comparisons were based on the most recent data available in published form from each state that specifically identified construction workers.[7,15–18] The blood lead level for which industry information could be determined varied by state. Data are presented for blood lead levels beginning at 1.93 μmol/L for Massachusetts, California, and Texas and at 1.21 μmol/L (25 μg/dL) for Maryland, New Jersey, and New York. We calculated the number of registrants in the construction industry per 100 000 employed male construction workers from employment figures from the Bureau of Labor Statistics' Current Population Survey using the appropriate years for each state.[19] Rates were calculated based on employment of male construction workers, because virtually all construction industry registrants were male.

Results

Of 381 individuals with blood lead levels of 1.93 μmol/L or greater reported to the Massachusetts Lead Registry, 311 (82%) were determined to have resulted from occupational exposure. Construction workers constituted 63% (n = 196) of this group. Deleaders comprised 60% (n = 118) of construction workers with blood leads exceeding 1.93 μmol/L; bridge and house painters accounted for almost all the rest (36%, n = 70).

Of 49 workers with blood lead levels of 2.90 μmol/L (60 μg/dL) or greater, 39 (80%) worked in construction. Twenty (51%) were bridge and house painters, and seventeen (44%) were deleaders.

The Massachusetts Registry was able to contact and interview 177 workers (57%). All interviewed deleaders (n = 51) reported that their blood test was part of an employer-sponsored program, compared with only 37% (n = 19) of other construction workers and 78% (n = 50) of nonconstruction workers.

Construction workers comprise a much larger proportion of registrants with occupational exposures in Massachusetts and Maryland (63% and 49%, respectively) than in California, New Jersey, New York, and Texas, where the proportions range from 2% to 6% (Table 1). The difference in the number of registrants in construction per 100 000 construction workers in each state is even greater. The Massachusetts rate of 123.4 was about twice that of Maryland (64.4) and 6 to 100 times higher than that of the other states.

Discussion

The finding that construction workers constitute 63% of occupationally exposed individuals with blood lead levels greater than 1.93 μmol/L in the Massachusetts Lead Registry sharply contrasts with reports from most other states. There are at least two likely explanations. First, the greater detection of elevated blood lead levels in Massachusetts construction workers is likely attributable to the mandatory blood lead testing of deleaders and structural painters described above. Second, the total number of deleaders, including those with elevated blood lead, may be greater, given the extensive, legally mandated deleading activity in the state. Residential lead paint abatement is required in Massachusetts whenever a child under the age of 6 lives in a dwelling unit with lead paint, a requirement virtually unique in the nation.[20] As a result, although compliance is not complete, a large number of residential units are deleaded each year, more than 4500 in 1991.[21]

Alternatively, the high proportion of construction workers in the Massachusetts Registry might be attributed to a possible relative absence of workers in

other lead-using industries. However, the rate of elevated blood lead levels of construction workers in the Massachusetts Lead Registry far exceeds the rates for other states, which suggests that increased detection and frequency of elevated blood lead levels are more likely explanations. Even the Massachusetts rate should be considered an underestimate, given the presumed low rate of monitoring among large groups of construction workers exposed to lead.

The large number of deleaders in the Registry is cause for concern. It underscores the hazardous nature of deleading and the need for both increased enforcement of deleading regulations and further research to evaluate alternative lead removal and lead control measures. Some states have banned dry scraping,[22,23] which continues to be a common form of lead removal in Massachusetts. The extent to which elevated blood lead levels in this industry can be attributed to the lead removal process or inadequate control techniques remains to be further evaluated.

It is notable that the majority of construction workers with blood lead levels greater than 2.90 μmol/L are not deleaders but workers in the structural painting industry—namely, bridge painters and house painters. Some of these workers may face higher levels of exposure or have less adequate controls than deleaders. In addition, they are much less likely than deleaders to participate in routine blood lead monitoring. Structural painters may be more likely to receive testing when their blood leads reach higher levels (i.e., when they are more likely to be symptomatic). Some states, including Massachusetts, have begun incorporating language specifying comprehensive lead protection measures in all public contracts for paint removal on bridges.

The Massachusetts deleading law appears to be more effective in generating blood lead monitoring among deleaders compared not only with structural painting workers, but also with nonconstruction workers, although the latter are covered by the OSHA lead standard, which requires blood lead monitoring. The better compliance in the deleading industry is likely due to the fact that the law requires not only monitoring of employees but also the reporting of results, and such reporting is a requirement for continued licensure. In developing new laws and regulations, officials should consider placing an affirmative obligation on employers to report blood lead test results to state authorities as an added measure for ensuring compliance.

The data from the Massachusetts Occupational Lead Registry, in conjunction with findings from lead registries in other states, indicate that hazardous lead exposure among construction workers is almost certainly grossly underreported nationally. The extent of overexposure to lead among construction workers demonstrated by the Massachusetts Lead Registry should not be surprising, given the history of lead paint use in this country. Concerns about protection for construction workers have been raised since long before 1978, when the OSHA Lead Standard for General Industry went into effect. This study supports the need for strict enforcement of the recently promulgated OSHA Lead Standard for Construction, which provides workers in this industry with new protections. □

The Adequacy of Prenatal Care Utilization Index: Its US Distribution and Association with Low Birthweight

Milton Kotelchuck, PhD, MPH

ABSTRACT

The proposed Adequacy of Prenatal Care Utilization Index is applied to data from the 1980 National Natality Survey to assess the adequacy of prenatal care utilization and its association with low birthweight in the United States. The index suggests that only 61.1% of women received adequate prenatal care, including 17.7% with more intensive care; 16.7% received inadequate care. More White women (63.4%) than Black women (51.9%) received adequate prenatal care. Low-birthweight rates were elevated among women with inadequate prenatal care and among those who received more intensive prenatal care. (*Am J Public Health.* 1994;84:1486–1489)

Introduction

The measurement of prenatal care utilization adequacy depends on the accuracy of the index used; previous efforts may have overestimated the adequacy of prenatal care utilization in the United States by incorrectly assessing utilization after enrollment. Elsewhere in this issue of the Journal, I discuss limitations of the Kessner/Institute of Medicine Index[1] and propose an alternative two-part Adequacy of Prenatal Care Utilization (APNCU) Index.[2]

In this paper I apply the APNCU Index to data from the 1980 National Natality Survey, a representative sample of US births. Characteristics of the database have been described previously.[3,4] The goals of this paper are to assess the adequacy of prenatal care utilization in the United States and its first-order association with low birthweight.

Distribution of Adequacy of Prenatal Care Utilization in the United States

The last column of Table 1 shows the distribution of adequacy of prenatal care utilization in the United States as judged by the two dimensions of the APNCU Index and by the summary (combined) index. Overall, 61.1% of US women received adequate or better prenatal care, including 17.7% with more intensive Adequate Plus care; 38.9% received less than adequate prenatal care, including 16.7% with Inadequate care. (The criteria used for these designations are described in Kotelchuck.[2])

"Adequacy of Initiation of Prenatal Care," or month prenatal care begins, shows the well-known prenatal care initiation pattern in the United States: 87.5% of women initiated care before month 5, and only 4.6% began after month 6 or not at all.

"Adequacy of Received Services," or percentage of recommended visits received (the dimension of prenatal care newly described by the APNCU Index), suggests a more mixed picture of prenatal care utilization. On a positive note, 68.5% of women received adequate or better prenatal care after initiation of care. Indeed, 22.2% received additional prenatal care visits beyond the number recommended by the American College of Obstetricians and Gynecologists.[5] Unfortunately, 31.4% of women received less than optimal care, with 6.7% receiving fewer than 50% of the recommended visits.

Table 1 also shows the adequacy of prenatal care utilization stratified by race. Black women had substantially poorer overall prenatal care utilization; almost twice as many Black women (27.8%) as White women (14.0%) received Inadequate care. The most profound racial difference is the delayed initiation of prenatal care within the Black community; 21.1% of Black women, compared with 10.5% of White women, began care after month 4. After initiation of prenatal care, there is less disparity but more variability in utilization; Black women were more likely than Whites both to receive too few visits and to receive more visits than the recommended number.

Table 2 shows the full distribution of the two dimensions of the APNCU Index. Women whose care was rated Inadequate (16.7%) generally did not receive Inadequate ratings on both dimensions; only 2.5% were rated Inadequate on both. Women with no care (1.0%; data not shown) were not the major contributors to the Inadequate ratings for either dimension.

Association of Prenatal Care Utilization with Low Birthweight

Table 3 examines the association of the two dimensions of the APNCU Index with low birthweight. (These are first-order associations; they are not meant to prove or disprove the impact of increased prenatal care utilization on improved birth outcomes. Such an analysis would require a much more sophisticated methodology than is possible in this paper.) There is a positive linear association between month of initiation of prenatal care and low-birthweight rates. Low-birthweight rates increased substantially for women who initiated prenatal care after the 4th month.

There appears to be a U-shaped association between recommended visits received and low-birthweight rates; both women with Inadequate ratings and those with Adequate Plus ratings had increased low-birthweight rates. The best birth outcomes were seen in women who started prenatal care in the first half of pregnancy and received between 50% and 109% of the recommended number of visits. Those women who were rated lowest on both dimensions had the worst birth outcomes (18.9% had low-birthweight babies), although this result might have been due to confounding with other concurrent social risks and premature delivery before enrollment in prenatal care. Women with no prenatal care had a low-birthweight rate of 26.7% (data not shown).

Table 4 reflects both the distribution of prenatal care utilization (Table 2) and the rate of low birthweight associated with that distribution (Table 3). It demonstrates the distinct distributions of adequacy of prenatal care utilization among all low-birthweight infants and among total births in the United States. The majority of low-birthweight births (63.0%) occurred to women with Adequate or Adequate Plus prenatal care. Women who received extra prenatal services (17.7%) had a disproportionate share of low-birthweight births (38.5%; crude relative risk, 2.17). Women with Intermediate or Adequate prenatal care had disproportionately fewer low-birthweight infants. Women with Inadequate care (16.7%) also had elevated proportions of low-birthweight births (24.5%). The 2.5% of women whose care was rated Inadequate on both dimensions had the most elevated relative risk, but these women accounted for only 5.3% of all low-birthweight

TABLE 1—Ratings Assigned to Births According to the Adequacy of Prenatal Care Utilization Index, by Maternal Race

	White, %	Black, %	All Births, %
Month of initiation of care			
7–9 or no care	4.0	7.0	4.6
5–6	6.5	14.1	7.8
3–4	34.3	40.5	35.4
1–2	55.1	38.4	52.1
% of recommended visits received			
0–49	5.5	11.6	6.7

infants in the United States (data not shown).

Discussion

The APNCU Index suggests a more somber picture of prenatal care utilization in the United States than do the other two major prenatal care indexes. The APNCU Index suggests that 61.1% of women in the United States receive adequate prenatal care, compared with the 65.9% suggested by the Kessner Index and the 77.9%[2] suggested by the trimester of prenatal care initiation. Similarly, the APNCU Index suggests that more women have inadequate care (16.7%) than is suggested by either the Kessner Index (7.7%) or the trimester of prenatal care initiation (4.6%). The lower rates of prenatal care utilization adequacy indicated by the APNCU Index reflect the index's more complete assessment and the added contribution of prenatal care utilization after initiation. Overall, the APNCU Index ratings imply that one in six American women have inadequate prenatal care and almost two in five have less than adequate care. These are truly disgraceful figures for our country.

Both the timing of initiation and the number of prenatal care visits contribute to the poor overall prenatal care utilization rates. The fact that care rated Inadequate on one of the APNCU Index's two dimensions is not generally rated Inadequate on the other suggests that recruiting women into the prenatal health care system and keeping them there may be two distinct phenomena. The APNCU Index suggests that late initiation of care is the more significant problem in the United States, which agrees with recent data from cross-national comparisons of prenatal care utilization.[6]

The poorer prenatal care utilization by Black women than by White women suggested by the APNCU Index is consistent with the results of other national analyses.[7–9] Delayed initiation of prenatal care, not received services, appears to be the principal reason for the racial disparity in utilization. That more Black women than White women receive Adequate Plus services can be interpreted positively as an indication of the health care system's responsiveness to higher-risk Black women; unfortunately, however, more Black women are also not receiving minimal prenatal care services.

The U-shaped association of low birthweight and prenatal care utilization indicated by the APNCU Index is clinically plausible and has been noted previously.[10] Extensive prenatal care visits have been linked to high-risk pregnancies.[11,12] But perhaps because the predominant Kessner Index has no classification for intensive prenatal care services, the association between low birthweight and prenatal care has been predominantly described in a more linear fashion, emphasizing poor birth outcomes directly related to poor prenatal care. Women who receive extra prenatal care visits are clearly a very high-risk group, but they are already known to health care providers. The efficacy of prenatal care interventions, rather than access, may be the important issue for these women. Their high proportion of low-birthweight births should make us somewhat sanguine about proposals to improve US infant mortality rates that simply recommend more prenatal care visits generally or for high-risk women only.

The relationship between prenatal care utilization and low birthweight is determined in part by the measure of prenatal care utilization. Given the elevated low-birthweight rates among women receiving Adequate Plus services, the weak correlations between the Kessner Index and birth outcomes reported in the public health literature may now be better appreciated.[11,13] The majority of low-birthweight births in the United States occur to women with adequate or better prenatal care utilization, irrespective of whether one uses the Kessner Index (52.2%), trimester of prenatal care initiation (70.1%), or the APNCU Index (63.0%) (data not shown). An Inadequate rating on the APNCU Index is, however, associated with a higher percentage of the total low-birthweight distribution (24.5%) than an Inadequate rating on the Kessner Index (14.9%) or the trimester of prenatal care initiation (8.0%). The ability of the APNCU Index to more accurately and comprehensively assess prenatal care utilization should enhance our understanding of the association between prenatal care utilization and birth outcomes in the United States. □

The Effect of Paternal Smoking on the Birthweight of Newborns Whose Mothers Did Not Smoke

Fernando D. Martinez, MD, Anne L. Wright, PhD, Lynn M. Taussig, MD, and the Group Health Medical Associates

ABSTRACT

We examined the relationship of paternal smoking habits to birthweight in a cohort of infants enrolled at birth (n = 1219). To assess validity of parental smoking reports, cord serum levels of cotinine were measured in 175 newborns. A mean birthweight deficit of 88 g was found in newborns of nonsmoking mothers whose fathers smoked more than 20 cigarettes/day. Only 2 of 138 newborns whose mothers said they were nonsmokers had cotinine levels indicating that their mothers were active smokers. Among infants of nonsmoking mothers, detectability of cotinine in cord blood was significantly correlated with the number of cigarettes smoked daily by fathers. These data suggest that fetal growth may be adversely affected when the mother is passively exposed to tobacco smoke during pregnancy. (*Am J Public Health.* 1994;84:1489–1491)

Introduction

There is strong evidence indicating that active maternal smoking during pregnancy is associated with reduced birthweight in the mothers' offspring.[1,2] Deficits ranging from 90 to 300 g have been reported. However, available data on a possible effect of mothers' passive exposure to cigarette smoke on birthweight are less convincing. MacMahon et al.[3] reported that infants whose fathers smoked had a mean birthweight 85 g less than that of infants whose fathers did not smoke. Martin and Bracken[4] reported that passive smoking by nonsmoking mothers was significantly related to delivering a low-birthweight newborn, after adjustment for confounding factors. Rubin et al.[5] found that fathers' smoking was associated with a mean reduction in birthweight of 6 g per cigarette smoked. It has been suggested, however, that a significant proportion of these effects were attributable to smoking mothers who were classified as nonsmokers based on their responses to questionnaires.[6,7]

The aim of this study was to determine the possible effect of paternal smoking on birthweight. To assess the influence of misclassification as a possible source of bias, levels of cotinine (a metabolite of nicotine) were measured in cord blood of a representative sample of the population.

Subjects and Methods

The study subjects were enrollees of the Tucson Children's Respiratory Study, a longitudinal study of risk factors for lower respiratory tract illnesses in infancy and childhood.[8] Newborns whose parents used one of the largest health maintenance organizations in Tucson, Arizona, were enrolled. Premature infants were not excluded if they were healthy. A total of 1596 infants were eligible, but participation was refused for 350 infants (22%). There were no statistically significant differences in terms of parental smoking, parity, maternal employment, or household size between families who refused to participate and those who enrolled their newborns into the study.[8] However, enrolled and refusal groups differed significantly in terms of marital status, parental age, parental education, and ethnicity.[8]

Information on birthweight, maternal and paternal education, number of previous births, duration of pregnancy, and ethnicity was obtained by study nurses while mother and newborn were still in the hospital. Each parent was given a questionnaire concerning, among other issues, his or her smoking habits. Specifically, mothers and fathers were asked whether they smoked regularly and the number of cigarettes smoked daily (none, 1–10, 11–20, and > 20). Because questionnaires were answered within the first month of life of the child (median = 15 days), parents who said they smoked were

[a]Adjusted for gestational age, gender, ethnicity, birth order, maternal and paternal education, and maternal age.
[b]Information on birthweight was not available for three infants; data on maternal smoking were unavailable for one infant. The number of cigarettes smoked per day was not available for 41 smoking mothers. Information about at least one confounder was unavailable for 33 subjects.
[c]Newborns whose mothers were single, separated, or divorced (n = 67) were not included. The number of cigarettes smoked per day was not reported for 18 smoking fathers.

TABLE 2—Multiple Regression Analysis for Children of Nonsmoking Mothers with Birthweight as the Dependent Variable (n = 907)

	Difference in Birthweight, g	95% CI
Gestational age	−166	−219, −113
Hispanic	−55	−135, 25
Other non-Anglo	−104	−257, 49
Birth order	78	45, 111
Paternal education	8	−70, 86
Maternal education	−52	−126, 22
Maternal age	6	0, 12
Paternal smoking	−34	−63, −5
Constant[a]	3607	...

Note. Coding for variables was gestational age in weeks: 40 weeks = 0; gender: males = 0, females = 1; Hispanic: no = 0, yes = 1; other non-Anglo: no = 0, yes = 1; birth order: first = 0, second = 1, third = 2, fourth + = 3; paternal and maternal education: >12 years = 0, ≤12 years = 1; maternal age in years: 30 years = 0; paternal smoking: nonsmoker = 0, 1–10 cigarettes/day = 1, 11–20 cigarettes/day = 2, >20 cigarettes/day = 3. CI = confidence interval.
[a]The constant represents the expected birthweight for an Anglo boy, first born to nonsmoking parents with college-level education; gestational age = 40 weeks and maternal age = 30 years. Coefficients indicate change in birthweight (in grams) when compared with the reference category in each group (with a value of 0).

considered to have smoked during pregnancy.

Cord blood specimens were collected for 87% of the enrolled infants; cord serum cotinine levels were measured by competitive radioimmunoassay[9] in a sample of 175 infants (14%). There was no significant difference in any social or demographic parameter between these 175 infants and the rest of the eligible population. The lower limit of detectability for the serum cotinine assay was 1 ng/mL.

Statistical Analyses

Birthweights were adjusted for possible confounders by standard regression procedures. The Mantel test was used to test for linear trends in proportions.[10] This procedure was chosen because it is particularly suitable for sparse data.[11] Logistic regression was used in the subgroup of infants who had cotinine measured to determine whether maternal and paternal smoking independently increased the proportion of infants with detectable cotinine levels.

Results

Relationship between Paternal Smoking and Birthweight

Duration of pregnancy was not significantly affected by either maternal or paternal smoking. There was a significant correlation between birthweight and the number of cigarettes smoked by the mother (Table 1). Newborns of mothers who reported smoking more than 20 cigarettes per day had a mean deficit of 273 g. When newborns of nonsmoking mothers were studied separately (Table 1), a significant trend for birthweight to decrease with increasing numbers of cigarettes smoked by the father was observed. Newborns of nonsmoking mothers whose fathers smoked more than 20 cigarettes per day had a mean deficit of 88 g. This association was independent of maternal and paternal education, birth rank, ethnicity, maternal age, duration of pregnancy, and sex. The independent contribution of these variables to birthweight among children of nonsmoking mothers is shown in Table 2.

Validation of Questionnaire Data and Assessment of Misclassification

To assess the validity of questionnaire data, cotinine levels were measured in cord serum of a representative sample of 175 newborns. The mothers of 37 of these subjects reported being smokers. Only 7 of these 37 infants (19%) had undetectable cotinine in cord blood. All 23 subjects whose mothers smoked more than 10 cigarettes per day had detectable cotinine levels, compared with half of those whose mothers smoked 1–10 cigarettes per day and 4.4% of those whose mothers were nonsmokers ($P < .0001$). Median (range) cotinine concentrations were 3.5 ng/mL (0–99 ng/mL) for newborns whose mothers smoked 1–10 cigarettes per day; 59 ng/mL (2–195 ng/mL) for newborns whose mothers smoked 11–20 cigarettes per day; and 55 ng/mL (14–239 ng/mL) for newborns of mothers who smoked more than 20 cigarettes per day. It is evident from the above data that no newborns of mothers who smoked 11 or more cigarettes per day had serum cotinine levels of <2 ng/mL. Moreover, all seven newborns of mothers who reported smoking 1–10 cigarettes per day and who had detectable serum cotinine had ≥2 ng/mL.

Cotinine levels were undetectable in 130 of 138 (94%) newborns whose mothers reported being nonsmokers, and an additional 6 subjects (4.3%) had serum cotinine levels at the lower limit of detectability for this assay (1 ng/mL). The remaining two subjects (1.5%) had cord serum cotinine concentrations of 23 and 101 ng/mL, respectively. These values were clearly within ranges found only among newborns of active smokers. Because values of 1 ng/mL were not seen among infants whose mothers reported being smokers, we estimated that in our population misclassification of smoking mothers as nonsmokers was approximately 1.5% (95% confidence interval = 0.5, 3.5).

We studied the relation between paternal smoking and detectability of cotinine in 130 infants of nonsmoking mothers (after excluding the 2 misclassified infants and those of an additional six mothers who were single, separated, or divorced). In this group, cord serum cotinine was detectable in only 2.7% (3 of 110) of the newborns with nonsmoking fathers, whereas cotinine was detectable in 15.0% (3 of 20) of the newborns whose mothers were nonsmokers but whose fathers smoked ($P < .05$). The frequency of detectable cotinine in cord blood was also strongly correlated with the number of cigarettes smoked by the father ($P = .001$). A logistic regression was performed with detectability of cord serum cotinine as the dependent variable and smoking by each parent (in four levels, as described previously) as the independent variable. Both maternal smoking ($P < .0001$) and paternal smoking ($P = .01$) were independent determinants of the presence of detectable cord serum cotinine levels.

Discussion

In this study we demonstrated a significant influence of paternal smoking on birthweight in newborns of nonsmoking mothers, and this effect was independent of several possible confounders. Our results are consistent with those of Haddow and collaborators,[12] who reported a deficit of 107 g in newborns of nonsmoking mothers who had serum cotinine levels of 1.1–9.9 ng/mL during pregnancy. Our findings also confirm the report by Rubin et al.[5] of a significant reduction in birthweight associated with paternal smoking. After controlling for confounders, they found that an infant born to a father who smoked 20 cigarettes per day had an average reduction in birthweight of 120 g. This compares well with our value of 88 g for an infant born to a father who smoked more than 20 cigarettes per day. Recent reports from Italy[13] and India[14] also suggest significant effects of paternal smoking on birthweight.

It has been suggested that the association between passive maternal smoking and birthweight is explained by underreporting of active maternal smoking.[6,7] To assess this possibility, we measured cotinine levels in cord blood in a representative sample of the study subjects. Only two infants (1.5%) of mothers who reported being nonsmokers had cotinine levels within the range of those found in newborns of smoking mothers. In both cases, the father was a nonsmoker. Thus, it is improbable that the small degree of underreporting of active smoking by mothers may account for our findings.

We cannot completely exclude the possibility that differences in life-style or nutritional status between persons exposed and unexposed to environmental tobacco smoke may explain our findings.[15] However, reports of lower birthweight in newborns whose mothers were exposed to environmental tobacco smoke during pregnancy come from countries with very different life-styles[5,12–14]; this fact argues against the possibility that a specific confounder or combination thereof may explain the consistent effects observed in these studies. We did not ask mothers about alcohol consumption during pregnancy, but Rubin et al.[5] and Haddow et al.[12] showed that this factor does not explain the relationship between the mother's exposure to environmental tobacco smoke and birthweight. Finally, other sources of exposure not considered in this study, such as presence of other smokers at home or in the workplace, seemed to be considerably less important than paternal smoking; only 2.7% of newborns of nonsmoking parents had detectable cord serum cotinine levels.

The clinical implications of reductions in birthweight such as those reported herein are not known. Birthweight is inversely correlated with both neonatal and postneonatal mortality.[16] The increased risk is not limited to low-birthweight infants, however; infants with birthweights of 3000–3499 g have infant mortality rates that are higher than those of infants weighing 3500–3999 g at birth.[16] Thus, it is conceivable that the reduction in birthweight caused by both active and passive maternal smoking may increase the risk for mortality during the first year of life.

Our study adds new evidence to the increasing body of information showing unfavorable effects of passive smoking on human health. Pregnant women should not only be advised to stop smoking; they should also be encouraged to avoid environments in which cigarettes are smoked by others. □

Intrauterine Cocaine, Lead, and Nicotine Exposure and Fetal Growth

Daniel R. Neuspiel, MD, MPH, Morri Markowitz, MD, and Ernest Drucker, PhD

ABSTRACT

Intrauterine tobacco, lead, and cocaine exposure often co-occur and may affect fetal growth and development, yet studies of gestational cocaine effects have not adequately measured lead or tobacco. In this anonymous survey, blood lead and urine cotinine levels were determined and mothers were queried about tobacco use. Eighteen cocaine-exposed mother–infant dyads had higher lead and cotinine levels than 46 random nonexposed dyads, regardless of reported cigarette smoking. Crude growth decrements in cocaine-exposed newborns were attenuated after control for lead and cotinine. Future studies of gestational cocaine effects should measure other toxic exposures with more precision. (*Am J Public Health* 1994;84:1492–1495)

Introduction

Gestational cocaine exposure has been associated with fetal growth[1] and infant behavioral deficits,[2] yet possible confounding from other risk factors[3,4] has not been fully explored. Tobacco and lead have also been associated with impaired fetal growth and brain development. Cocaine users may be exposed to lead in older substandard housing associated with poverty and may have both active and passive tobacco exposure. Further, tobacco and lead may interact: active smokers[5–7] and their children[8–11] have higher lead levels, with a dose–response gradient between parental smoking and child lead levels[12,13]; newborn lead levels have been correlated with the duration of maternal smoking.[14] This investigation hypothesized that cocaine-exposed newborns have more lead and tobacco exposure and that cocaine-associated effects on the growth of newborns are partly explained by lead and/or tobacco exposure.

Methods

Over 2 months in 1992, parturient women in a public hospital provided urine samples for routine clinical testing, the discarded portions of which were separated in two for drug and cotinine measurement. At delivery, umbilical cord blood was placed in a heparinized lead-free tube for lead assay. After study staff obtained clinical information from hospital records, the study urine and blood samples were given a number code and other identifiers were removed. Urine samples were tested in women proceeding to singleton deliveries. When more than one urine sample was provided, the earliest sample was used.

One urine sample was assayed for cocaine, benzoylecgonine, opiates, methadone, cannabinoids, and amphetamine by the EMIT method.[15] Two randomly selected comparison dyads with negative toxicology were chosen for each drug-positive case. All women giving birth were routinely asked about cocaine and tobacco use during pregnancy by clinical staff, independent of this study. The other study urine sample was assayed for cotinine (a metabolite of nicotine) by radioimmunoassay, and creatinine was determined to correct for variation in urine volume.[16]

Whole blood lead was measured by atomic absorption spectrophotometry in a laboratory participating in proficiency testing programs of the Centers for Disease Control and New York State. The 95% confidence limit for blood lead is ± 1 μg/dL.[17]

Statistical analysis was done with SYSTAT software.[18] This investigation was approved by the Institutional Review Board of Montefiore Medical Center and by the New York City Health and Hospitals Corporation. Because study data were collected anonymously, informed consent was waived.

Results

Discard urine specimens were obtained from 237 (41%) of the 581 mothers having singleton deliveries during the study period. Cocaine-positive cases were identified from study assays (10 of 237 tested), clinical tests (7 additional cases of 47 tested), or maternal history (1 additional case). Five case subjects with study urine samples positive only for drugs other than cocaine were excluded. Forty-six comparison subjects were chosen from 220 dyads with both negative study toxicology and no self-report of drug use. Of 18 cocaine-positive dyads, 6 were tested for both cotinine and lead, 6 only for cotinine, and 6 only for lead. Of 46 cocaine-negative dyads, 20 had both lead and cotinine levels, 13 had only cotinine, and

12 had only lead. There were no differences between the subjects with and without anonymous urine samples either in the proportion of infants clinically tested for drugs (6% and 9%, respectively) or in the proportion of clinical tests that were positive for cocaine (29% and 32%, respectively); the chi-square test was nonsignificant for each.

Demographic, pregnancy, and newborn information is in Table 1. Of 64 mothers, 56% were Hispanic, 31% African-American, 5% White, 6% Asian, and 2% other ethnicity. The mean lag time from urine collection to testing was similar in both exposure groups.

Lead and cotinine levels (Table 2) were higher in the cocaine group, in which cotinine levels were elevated both among cigarette smokers and nonsmokers. Lead levels differed between admitted smokers (mean = 5.2 μg/dL; 95% confidence interval [CI] = 4.5, 5.9) and nonsmokers (mean = 3.5 μg/dL; 95% CI = 3.0, 4.0; $P = .001$).

Multiple linear regression (Table 3) was used to evaluate the independent effects of cocaine, lead, and cotinine on fetal growth after control for gestational age. The apparent effects of cocaine on birthweight and head circumference were diminished after consideration of cotinine levels; smoking history explained fewer cocaine effects than cotinine and was a weaker confounder. Lead exposure explained some of the cocaine-related decrement in all three growth measures, but it had less effect than cotinine on weight and head circumference. Separate models demonstrated no confounding of cocaine effects on fetal growth by race, maternal age, gravidity, or parity. Nine regressions were conducted with each of the three dependent variables.

TABLE 1—Characteristics of Mothers and Newborns, by Cocaine Exposure

	Group				
	Cocaine Exposed (n = 18)		Comparison (n = 46)

[a]Because cotinine levels were skewed, log transformation was done before statistical calculations; geometric means are reported.

Discussion

Many methodologic difficulties exist in studying cocaine effects on the fetus.[2] The effects of concurrent exposures are of particular importance because cocaine users share many other potential perinatal risk factors.

Cocaine-exposed newborns may be exposed to more ambient lead. Tobacco exposure may also raise lead levels by small-airway damage and more hand-to-mouth behavior.[13] Nutritional factors may predispose cigarette smokers and cocaine users to higher lead levels via inadequate iron or calcium intake. In addition, crack smoking increases lung permeability due to chronic epithelial damage,[19] which may increase absorption of airborne lead. Maternal alcohol intake has been related to lead levels, independent of smoking.[9] Also, behavioral manifestations of chronic lead exposure may lead to more cocaine use.

Lead and cocaine have a demonstrated neurotoxicological interaction in animals.[20–22] Intrauterine lead[23] and tobacco[24] have been associated with later cognitive and behavioral problems. Consideration of these exposures as confounders is therefore important in studying the long-term neurodevelopmental effects of intrauterine cocaine.

Tobacco affects the fetus,[25] and cocaine-using women actively smoke more cigarettes[3,4] and may be exposed to more passive tobacco smoke. The reported number of cigarettes smoked per day weakly correlates with urine cotinine levels.[26] These data show that reported maternal smoking inadequately controls for the effects of tobacco on fetal growth compared with quantitative urine cotinine levels.

Incomplete cohort participation in the current study was primarily due to lack of 24-hour supervision of specimen collection. Cocaine users may have been reluctant to provide urine specimens because of fearing punitive consequences, even though they were unaware of the study. However, nonparticipants had similar rates of clinical toxicology testing. The negative-toxicology group may have included some clandestine cocaine users, because the urine tests in this study were only sensitive for use within 3 days, but then the differences detected may underestimate the truth.

The groups differed in several health and social factors that could affect growth

[a]Separate regression equations (using model $y = x_0 + x_1 + x_2 \ldots x_n$) each include a constant (x_0), cocaine exposure (x_1), and gestational age (x_2) as independent variables.
[b]Change in dependent variable associated with cocaine exposure, controlling for other independent variables in model.
[c]P value for effect of cocaine exposure.

outcomes. Although separate regressions showed no effects of these factors, there was insufficient power to control for them simultaneously or to examine for statistical interaction. There was no information on important factors such as alcohol, cocaine dose, or exposure period; and the dichotomization of cocaine exposure may have diminished the true effects. It was not apparent why birth length was less influenced by cotinine than were the other growth parameters.

Many factors associated with cocaine use in the environments of pregnant women and young children may affect development and behavior. Blaming cocaine alone for adverse outcomes may have negative maternal consequences, such as unnecessary termination of pregnancy.[27] The labeling of cocaine-exposed children as irreparably damaged "crack kids" may confer a self-fulfilling prophecy of failure and ignore other remediable causes of developmental impairment.[28,29] Cocaine users and their children have many other risks that need more accurate consideration. A one-dimensional emphasis on cocaine is an inaccurate causal explanation, leading to inappropriate public health policies. □

Selected Antepartum Medical Complications and Very-Low-Birthweight Infants among Black and White Women

Michael DeBaun, MD, MPH, Diane Rowley, MD, MPH, Michael Province, PhD, Joseph W. Stockbauer, MS, and F. Sessions Cole, MD

ABSTRACT

This study estimated the risk of very-low-birthweight delivery among Black and White women with selected treatable antepartum medical conditions. A logistic regression model was applied to a retrospective, population-based data set identified by computerized, linked birth certificate and maternal hospital discharge records. For Black mothers, the adjusted odds ratio for very-low-birthweight delivery was statistically significant for essential hypertension and urinary tract infection. For White mothers, the adjusted odds ratio was statistically significant for essential hypertension, urinary tract infection, pregnancy-induced hypertension, and diabetes mellitus. Public policy designed to reduce the risk of very-low-birthweight delivery must include strategies for attenuating the impact of treatable antepartum medical conditions. (*Am J Public Health.* 1994;84: 1495–1497)

Introduction

Recently, Kempe et al. suggested that 80% of the excess risk of very-low-birthweight (<1500 g) delivery among Black infants results from four maternal medical complications: chorioamnionitis or premature rupture of membranes, idiopathic preterm labor, hypertensive disorders, and hemorrhage.[1] With the exception of hypertensive disorders, none of the antepartum maternal medical conditions studied by Kempe et al. can be effectively treated to prevent preterm delivery. We investigated whether potentially treatable maternal medical conditions increase the risk of very-low-birthweight delivery. In the data available for this study, very low birthweight serves as the best available surrogate for preterm delivery.

Methods

The study population consisted of subsets of infants born to St. Louis County and Kansas City, Mo, residents during the period 1983 through 1985. We identified these infants from the linked birth certificate and maternal hospital discharge data set maintained by the Center for Health Statistics of the Missouri Department of Health. This linked data set provided more complete information on maternal medical conditions than birth certificates alone.[2,3]

The study was restricted to 272 Black and 292 White singleton, live-born, very-low-birthweight (<1500 g) infants and 9820 Black and 36 763 White infants of normal birthweight (>2499 g). We excluded infants with birthweights of 1500 to 2499 g to reduce the number of growth-retarded infants in the data set and sharpen the focus on preterm delivery.[4] Linked birth and maternal discharge records were available for 11 185 Black and 38 574 White births (70% and 80% of total births, respectively) (Table 1). For both races, the linked and nonlinked populations had similar demographic characteristics (Table 1).

All complications were recorded in the *International Classification of Diseases,* 9th Revision, Clinical Modification (ICD-9-CM) coding system. The complications were divided into the following categories: diabetes mellitus (ICD-9-CM codes 250 to 2500, 2502 to 2508, 6480), gestational diabetes (ICD-9-CM code 6488); pregnancy-induced hypertension (ICD-9-CM codes 6423 to 6429), essential hyperten-

[a]Weight in kilograms divided by height in meters squared. The Centers for Disease Control and Prevention classifies body mass index less than 18 as extremely underweight.

TABLE 2—Crude and Adjusted Odds Ratios for Very-Low-Birthweight (<1500 g) Delivery, by Race: St. Louis County and Kansas City, Mo, 1983 through 1985

Maternal Medical Condition	Odds Ratio (95% Confidence Interval)			
	Blacks		Whites	
	Crude	Adjusted[a]	Crude	Adjusted[a]
Diabetes mellitus	0.8 (0.3, 2.7)	1.0 (0.3, 3.3)	2.5 (1.2, 5.4)	2.7 (1.2, 6.2)
Gestational diabetes	1.2 (0.3, 4.9)	1.6 (0.4, 6.5)	1.3 (0.3, 5.2)	1.5 (0.3, 6.3)
Essential hypertension	3.3 (1.3, 8.2)	4.9 (1.9, 12.8)	4.5 (1.4, 14.3)	5.2 (1.6, 17.0)
Pregnancy-induced hypertension	1.6 (1.0, 2.4)	1.6 (1.0, 2.6)	3.9 (2.7, 5.5)	4.2 (2.9, 6.0)
Urinary tract infection	3.1 (1.9, 5.0)	2.8 (1.6, 4.7)	6.4 (4.0, 10.5)	5.6 (3.3, 9.2)

[a]Adjusted for parity, body mass index, maternal age, marital status, cigarette smoking, educational attainment, and prenatal care.

sion (ICD-9-CM codes 4010 to 4019), and urinary tract infections (ICD-9-CM codes 590 to 5999, 595 to 5909, 599.0, 6466).

For each selected maternal medical condition, we estimated crude and adjusted odds ratios (with 95% confidence intervals) of the risk of having very-low-birthweight infants for Blacks and Whites separately because of the race-specific impact of sociodemographic factors. We used a logistic regression model to determine the adjusted odds ratio for each maternal medical complication and to determine the effect of race for each such complication after accounting for the effect of previously identified confounders of very-low-birthweight delivery. These confounders, obtained from the birth certificate, were parity (<3, ≥3), body mass index (weight in kilograms divided by height in meters squared) based on prepregnancy weight and height,[5] maternal age (<18 years, 18 through 34 years, >34 years), marital status (single, other), cigarette smoking during pregnancy (present, absent), educational attainment (completed <12 years of school, completed ≥12 years of school), and prenatal care (Kessner index: adequate, inadequate).[5]

Results

The prevalences of delivery of very-low-birthweight infants were 2.4% for Blacks and 0.8% for Whites (see Table 1). For normal-birthweight infants (>2499 g), Black mothers had higher rates (per 1000 live births) of the following antepartum medical conditions than did White mothers: gestational diabetes (6.9 vs 5.8), diabetes mellitus (13.0 vs 8.7), essential hypertension (10.3 vs 2.3), pregnancy-induced hypertension (124.1 vs 35.43), and urinary tract infection (65.5 vs 10.8).

Among Black mothers, both the crude and adjusted odds ratios and 95% confidence intervals for risk of very-low-birthweight delivery were greater than 1.0 for essential hypertension and urinary tract infection (see Table 2). Although neither the adjusted nor the crude odds ratio for pregnancy-induced hypertension was statistically significant for Black mothers, the magnitude of the point estimates suggests that the complication may be clinically relevant.

Among White mothers, the crude and adjusted odds ratios and 95% confidence intervals for very-low-birthweight delivery were greater than 1.0 for each condition except gestational diabetes. White mothers with pregnancy-induced hypertension had a greater risk of very-low-birthweight delivery than Black mothers ($P = .03$). There were no statistical differences between the risk of very-low-birthweight delivery in Blacks and Whites for gestational diabetes ($P = .90$), diabetes mellitus ($P = .30$), essential hypertension ($P = .31$), or urinary tract infection ($P = .24$).

Discussion

Maternal medical complications in these data contribute to the risk of very-low-birthweight delivery and vary in estimated effects among Black and White mothers. Essential hypertension among Black mothers and urinary tract infection among White mothers were associated with the greatest risk of very-low-birthweight delivery.

In a similar population-based study, Kempe et al.[1] also found a significantly increased risk of very-low-birthweight delivery associated with maternal conditions in data abstracted from medical records. The maternal conditions reported, however, typically result in delivery within hours or days after diagnosis. In contrast, we selected conditions that do not immediately precipitate delivery since they are more amenable to medical interventions.

Our study design had several limitations inherent in linked record data sets. Objective parameters were not used to define each maternal medical complica-

tion since all maternal conditions were identified from medical discharge diagnoses. Another limitation was the inability to assess the effect of medical interventions on each maternal condition. In addition, we were unable to account for conditions that occurred early in the pregnancy but resolved, since the maternal conditions were based on hospital maternal discharge diagnosis at the time of birth. Furthermore, we could not detect the effect of maternal medical conditions at different gestational ages, since gestational age was not consistently and accurately measured. Despite these limitations inherent in linked record data sets, previous studies with similar study designs have provided important findings regarding the effects of maternal smoking on infant mortality and preterm delivery.[6,7]

We conclude that treatable maternal antepartum medical complications contribute significantly to the risk of very-low-birthweight delivery among Black and White mothers but vary in estimated effects by race. Future research in maternal and child health is warranted to assess the impact of treating maternal conditions associated with very-low-birthweight delivery. □

Infant Mortality and Related Risk Factors among Asian Americans

Hallie W. Morrow, MD, MPH, Gilberto F. Chávez, MD, MPH, Peggy P. Giannoni, MA, and Rugmini S. Shah, MD

ABSTRACT

To examine differences in perinatal health among nine Asian ethnic subgroups, a descriptive epidemiological study was conducted using linked birth/infant death certificates for 1982 to 1987. When compared with Whites, Asians had a lower proportion of young mothers, unmarried mothers, and women who received first trimester prenatal care; a higher proportion of foreign-born mothers; and a different birthweight distribution. A great deal of heterogeneity was found in risk factors and infant mortality rates among the various Asian ethnic subgroups. Paradoxically, although Asian ethnic subgroups had a higher perinatal risk profile, they had more favorable birth outcomes than did Whites. (*Am J Public Health.* 1994;84:1497–1500)

Introduction

The Asian population in the United States has grown significantly in recent years.[1,2] The large majority of Asian-American births occur in only a few states, and more than 40% of them occur in California alone. Yet we know very little about the specific perinatal health status and risk factors of the different Asian ethnic subgroups, particularly the growing Southeast Asian populations.

In the United States, Asians overall have a slightly lower infant mortality rate than do Whites (i.e., the non-Hispanic White population).[3] However, Asians do not appear to be a homogeneous group in this regard. During 1983 and 1984, reported infant mortality rates varied considerably among some of the Asian ethnic subgroups studied in California and nationwide.[3] Overall, Japanese had the lowest infant mortality rates, followed by Chinese and Filipinos.[4,5] Specific information on infant mortality rates for other Asian ethnic groups is lacking.

Our study examines the prevalence of selected risk factors, the birthweight distribution, and the infant mortality experience among nine Asian ethnic subgroups in California between 1982 and 1987.

Methods

Data for this study were obtained from the California Birth Cohort file, a computerized record of linked birth/infant death certificates. Further information on this file has been published elsewhere.[6–8] Included in the analysis were all infants delivered alive from 1982 through 1987 whose mothers were identified as belonging to any of nine Asian ethnic subgroups (Cambodian, Chinese,

Filipino, Japanese, Korean, Laotian, Thai, Vietnamese, and Other Unspecified Asians). Excluded were infants born to mothers who were not California residents at the time of delivery (0.17%), infants whose birthweights were below 500 g (0.06%), and multiple births (1.57%).

The analysis was limited to risk factors for which reliable data were available. Parity, gravidity, and gestational age were not included because the reliability of the information available for meaningful analysis was questionable. Maternal education was not collected in California during the study period. Neonatal (<28 days), postneonatal (28 days to 364 days), and infant (0 to 364 days) mortality rates per 1000 live births were calculated, as were birthweight-specific mortality rates for all groups. Relative risks and 95% confidence intervals[9] were also calculated using Whites and all Asians as reference standards when comparing outcomes. Epi-Info,[10] SAS,[11] and Syntax[12] computer programs were used for the analysis.

Results

Overall, the prevalence of teenage births was lower for Asians than for Whites (4.3% vs 8.8%) (Table 1). Chinese and Koreans had remarkably low percentages of births to teenage mothers (0.7% and 1.0%, respectively), but Laotians had a very high proportion of such births (14.2%). Asians had a higher proportion of births to mothers 35 years of age and older than did Whites (13.6% vs 8.2%). This higher prevalence of older mothers

Note. Excludes multiple births, non-California residents, infants with unknown birthweights, and infants under 500 g. Mortality rates are per 1000 live births; relative risks (RRs) and confidence intervals (CIs) are birthweight adjusted. Rates not presented for cells with fewer than five events.
Source. California Department of Health Services, Birth Cohort File, 1982 to 1987.

was true for all the Asian subgroups except Koreans (7.6%). Additionally, more Asian mothers than White mothers were giving birth after the age of 39. Laotians and Cambodians, the groups with the highest percentage of teenage births, also had the highest percentage of births among women 40 years of age and older.

Compared with Whites, Asians had a lower proportion of women who received prenatal care in the first trimester of pregnancy and a higher proportion of women who received no prenatal care (Table 1). Only about 50% of Laotian and Cambodian women received prenatal care in the first trimester. In addition, these groups had the highest percentages of women who received no prenatal care and whose prenatal care history was unknown.

Asian mothers overall were nine times more likely than Whites to have been born outside the United States (Table 1). In several of the Asian subgroups—Vietnamese, Korean, Laotian, Cambodian, and Thai—essentially all the mothers were women who had immigrated to this country.

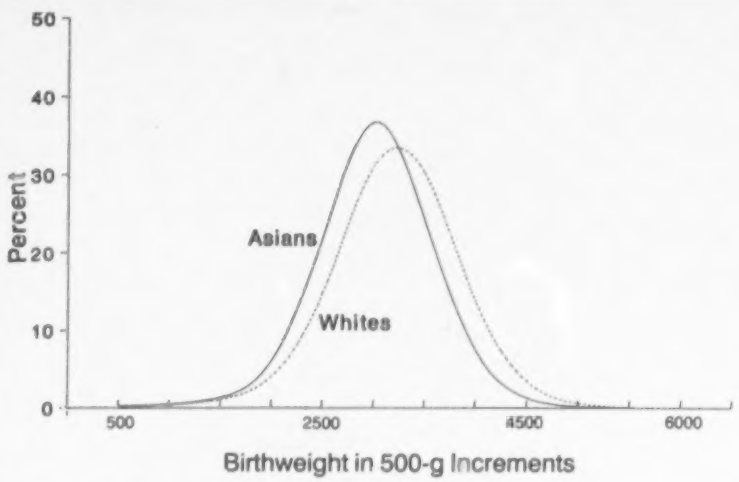
As a group, Asian mothers were less likely to be unmarried than White mothers (7.7% vs 16.7%) (Table 1). Each of the specific Asian subgroups also had a lower prevalence of unmarried mothers than Whites did. Koreans and Chinese had the lowest prevalence of unmarried mothers (1.7% and 3.1%, respectively); Filipinos and Cambodians had the highest prevalence (11.1% and 15.0%, respectively).

There were more low-birthweight infants (<2500 g) born to Asians than to Whites (5.2% vs 4.2%) (Table 2). This was true for all the Asian subgroups except Chinese, for whom there was no difference, and Koreans, who had fewer low-birthweight infants than Whites did. Examining the differences between all Asians combined and Whites by 500-g increments, we observed that the birthweight distribution for Asians was different than that for Whites and appeared to be shifted toward lower birthweight infants (Figure 1).

Asians as a group and the Filipino, Japanese, and Cambodian subgroups had significantly lower infant mortality risks than Whites (Table 3). The Thai and Laotian subgroups had slightly, but not statistically significant, elevated risks for infant mortality. Neonatal mortality was significantly lower for Asians as a group and for the Filipino and Japanese subgroups. The risks for postneonatal mortality were significantly lower for Asians as a group and for the Filipino, Vietnamese, Korean, Japanese, and Cambodian subgroups. After adjusting for birthweight, we found that Asians had lower overall neonatal, postneonatal, and infant mortality rates than did Whites.

Discussion

We showed a high degree of variation among the various Asian ethnic groups for maternal risk factors. Additionally, we observed that ethnic-specific differences in birthweight distributions, which have been reported for Chinese and Southeast Asian infants,[13–15] exist overall among several Asian ethnic subgroups when compared with Whites. We believe that our most remarkable finding was that even with great variability in the frequency of risk factors among the various Asian subgroups, the variability in birth outcomes is relatively small. In addition, despite their higher frequency of risk factors, Asians overall had significantly better birth outcomes than did Whites. Many factors could contribute to this finding, including differences in education, acculturation, nutrition, access to and content of prenatal care, life-style, family structure, social support, and underreporting. This apparent epidemiological paradox deserves further investigation since much may be learned from those ethnic groups that, despite serious disad-



Note. Excludes multiple births, non-California residents, and infants under 500 g.

FIGURE 1—Percentage distribution of live births by birthweight and race/ethnicity: California, 1982 to 1987.

vantages, are able to have healthier babies.

The high proportion of foreign-born Asian mothers in our study emphasizes the need for developing culturally appropriate multilingual prenatal care and health care services for this growing population. Larger sample sizes are needed to examine the differences in infant mortality risks between US- and foreign-born mothers with respect to acculturation and socioeconomic status.

Our study emphasizes the need for continued analysis of ethnic-specific perinatal health data to assess community needs adequately and to target health education efforts and intervention strategies to the groups at highest risk for suboptimal pregnancy outcomes and to those with the highest need for services. □

The Perinatal and Infant Health Status of Native Hawaiians

Edith C. Kieffer, PhD, MPH, Joanne M. Mor, MS, and Greg R. Alexander, MPH, ScD

ABSTRACT

Hawaii vital record data for 1979 through 1990 were analyzed to examine potentially differing relationships between maternal and infant risks and outcomes in native Hawaiian and White infants. Despite high rates of inadequate prenatal care and teenage and unmarried childbearing, the Hawaiian low-birthweight rate was below the US average. Hawaiian infants experienced an elevated risk of mortality, particularly among those of normal birthweight during the postneonatal period. Public health initiatives to reduce infant mortality must go beyond preventing teenage pregnancy and low birthweight to address Hawaiian infants' unique pattern of risk factors and the social and economic environment in which such risks abound. (*Am J Public Health.* 1994;84: 1501–1504)

Introduction

The indigenous people of Hawaii experience higher rates of morbidity and mortality from chronic diseases than do other ethnic groups in Hawaii and the United States.[1–5] Risks for diabetes and hypertension are particularly high among Native Hawaiian women and increase with age.[3,4] Less is known about the health status of Hawaiian infants. Recent reports have noted high rates of teen pregnancy and unmarried childbearing but relatively low rates of low birthweight among Hawaiian infants.[6,7] Similar patterns have been noted for American Indian and Mexican-American populations.[7,8] Such findings have stimulated discussion of protective factors that may offset the presumed higher risk of low birthweight.[9–11]

This study examined birthweight and gestational age, as well as rates and causes of mortality during the first year of life, for Hawaiian infants. Variations in maternal characteristics and health status indicators between Hawaiian and White infants born in Hawaii were investigated to identify the potentially differing role of maternal sociodemographic risk factors in these populations.

Data and Methods

Data were derived from Hawaii's linked live birth–infant death vital record files for 1979 through 1990. Data for the 12-year period were combined to minimize unstable fluctuations associated with small numbers of events and unusual, short-term trends. There were no appreciable temporal trends in birth outcomes over the period. All single live births to Hawaii resident mothers who identified themselves on the birth certificate as of Hawaiian, part-Hawaiian, or Caucasian ancestry were included in the study population. In this analysis, the category Hawaiian includes mothers with any Hawaiian ancestry, following common practice in the state.[12] An estimated 2% to 5% of these women are of unmixed Hawaiian ancestry.[5] A total of 117 005 births, including 66 840 White and 50 165 Hawaiian infants, were analyzed.

After imputing for missing values,[13] gestational age data, based on date of last normal menses, were available for 96.8% of the cases. Because gestational ages are typically less reliably reported, caution should be used in their interpretation. Less than 5% of the data for the other variables in the study were missing.

The significance of the bivariate relationships between maternal characteristics and infant outcomes was tested with chi-square and *t*-test statistics. Multiple logistic regression analyses were used to estimate associations between the independent effects of maternal characteristics and infant outcomes.[14]

Results

Maternal characteristics are defined and summarized in Table 1. Forty percent of Hawaiian mothers were unmarried, in comparison with 13% of White mothers. Hawaiian women had their first births at earlier ages than White mothers and had higher parities at each age level. Hawaiian women were four times more likely to have their first child, and three times more likely to have one or more previous children, before they were 18 years old. White women were more likely to have their first child after 29 years of age. Hawaiian women had lower levels of educational attainment, and only 56% received adequate levels of prenatal care. More than half of Hawaiian mothers resided in rural areas, in comparison with

Perinatal condition–specific IMR (No.)	4.3 (214)	2.5 (170)	<.01
SIDS-specific IMR	1.6 (80)	0.8 (53)	<.01
Other cause IMR	0.6 (32)	0.4 (28)	>.10

Note. Rates are per 1000 live births. IMR = infant mortality rate; SIDS = sudden infant death syndrome.
[a]Based on Brenner.[19]

a third of White mothers. Almost 90% of White mothers but only 6% of Hawaiian mothers were born outside of Hawaii. Because of extreme collinearity, this variable was excluded from subsequent analyses.

Table 2 summarizes measures of birthweight, gestational age, and infant mortality. The low-birthweight percentage for Hawaiian infants was 6.6, with very-low-birthweight infants accounting for 1% of births. Hawaiian percentages were below the 1990 US average but were significantly higher than rates for White infants.[7] Hawaiian infants were less likely to be born at high birthweights, and their mean birthweight was 125 g lower than that of White infants. Hawaiian infants were significantly more likely to be preterm and had almost double the risk of very preterm birth. Hawaiian infants were more likely to be small for gestational age and had slightly but significantly shorter mean gestational age.

Hawaiian infants experienced significantly higher infant mortality, including a postneonatal mortality rate that was double that of White infants. Higher infant mortality rates for Hawaiians were observed for every major cause of death. Perinatal conditions accounted for the greatest proportion of deaths to Hawaiian infants, followed by congenital anomalies and sudden infant death syndrome. Mortality rates from infectious diseases and injuries were two and three times the rates for White infants, respectively.

When birthweight and gestational age-specific infant mortality rates were examined, the mortality differential between ethnic groups was significant only for infants of normal birthweight and gestational age (Table 3). Differences between Hawaiian and White infants in rates of birthweight and gestational age-specific neonatal mortality were not significant. However, Hawaiian infants of moderately low birthweight and normal birthweight were almost twice as likely to die in the postneonatal period as White infants in the same birthweight categories. Postneonatal mortality rates were significantly higher for Hawaiian infants of normal gestational age.

Hawaiian infants remained at increased risk of low birthweight, preterm delivery, and neonatal and postneonatal mortality after logistic regression analysis accounted for the effects of maternal sociodemographic and prenatal care use characteristics (Table 4).

Discussion

This study contributes additional evidence of the discrepancy in health status between indigenous people of the United States and more recent residents.[8,15] The most common measure of

Hawaiian	1.18 (1.11, 1.26)	1.38 (1.31, 1.45)	1.23 (1.01, 1.51)	1.42 (1.10, 1.85)

Note. The reference group was as follows: age 18–29 years, para 1–4, married, average educational attainment, received subadequate prenatal care, urban residence, White (see Tables 1 and 2 for definitions).

infant health status, low birthweight, is not excessively high in this population. It is difficult to assess the public health significance of the modest increase in risk among Hawaiian infants for low birthweight, particularly given the large number of cases in this analysis. However, neonatal and postneonatal mortality rates are higher than would be expected given the percentage of low birthweight. Indeed, the ethnic gap in mortality between White and Hawaiian, American Indian, and Black infants is widest for infants born at normal birthweights and gestational ages.[8,15]

Common maternal risk factors, including age, parity, education, and prenatal care use, did not account for the excess risk of Hawaiian infant mortality. While many Hawaiian mothers reside in geographically isolated rural areas that have poor access to health care services, rural residence was not a significant factor in explaining ethnic differences in infant health status.

Maternal height and weight, tobacco and alcohol use, and other measures of maternal poverty and chronic disease were not available for the study population. Data from 1988 through 1990 birth certificates indicate that 20% of Hawaiian and 13% of White mothers reported smoking during pregnancy, a discrepancy that, if accurate, could account for some of the variation in birthweight between Hawaiian and White infants. Previous studies have noted that the mean height of Hawaiian mothers approximates that of White mothers in Hawaii, while mean weight and weight gain in pregnancy are higher.[16] Given the high prevalence of hypertension, diabetes, and asthma among Hawaiian women of childbearing age, the possible role of chronic diseases in the pregnancy outcomes of Hawaiian women deserves attention.

Higher Hawaiian postneonatal mortality rates are congruent with classic public health theories relating the risk of postneonatal death to poverty and environmental hazards. The increased risk of mortality from such preventable causes as infectious disease and injury among Hawaiian infants has been documented

previously.[17] Yet, intensive public health initiatives to reduce infant mortality in Hawaii and elsewhere have focused on the reduction of teenage pregnancy and low birthweight. High parity among older Hawaiian women and higher rates of mortality for Hawaiian infants of normal birthweight and gestational age suggest that improvement of maternal and infant health status for the indigenous people of Hawaii will necessitate a better understanding of their unique pattern of risk factors and interventions that address the social and economic environment in which such risks abound. □

Call for Student Papers on Preventive Medicine

The American College of Preventive Medicine, the Association of Teachers of Preventive Medicine Foundation, the Association of American Medical Colleges, the Association of Preventive Medicine Residents, the journal *Preventive Medicine,* and the Ulrich and Ruth Frank Foundation for International Health announce their annual competition for the best paper in preventive medicine by a medical student. The prize for the best paper is $1000 and publication in *Preventive Medicine.* The awardee will also be honored at Prevention '95, the annual meeting of the American College of Preventive Medicine and the Association of Teachers of Preventive Medicine, to be held in New Orleans, La, in spring 1995.

All prevention-oriented topics will be considered; papers addressing the implementation of clinical preventive services are encouraged.

All submissions must be received by *November 8, 1994.* For more information, send a self-addressed, stamped envelope to Mirza I. Rahman, MD, MPH, Department of Preventive Medicine, HSC Level 3 Room 086, Stony Brook School of Medicine, Stony Brook, NY 11794-8036.

Pregnancy Risk Factors and Birth Outcomes in Washington State: A Comparison of Ethiopian-Born and US-Born Women

Haimanot Wasse, MPH, Victoria L. Holt, PhD, and Janet R. Daling, PhD

ABSTRACT

This study compared birth outcomes of three cohorts of women with singleton live births in Washington State between 1980 and 1991: all Black Ethiopian-born women (n = 264) and samples of US-born Black (n = 526) and White (n = 546) women. Ethiopians were older, more likely to be married, and less likely to smoke than were US-born women, and they were less likely to have anemia than US-born Blacks. The adjusted low-birthweight risk among Ethiopians was similar to that of US-born Blacks (relative risk [RR] = 0.9) and Whites (RR = 1.1). Ethiopians were more likely to have high-birthweight infants than were US-born Blacks (RR = 4.0). Cultural and behavioral etiologies may explain these favorable birth outcomes. (*Am J Public Health.* 1994;84: 1505–1507)

Introduction

Blacks born outside of the United States have generally been found to have more favorable pregnancy outcomes in America than their US-born counterparts, with lower rates of prematurity and higher birthweights.[1–5] The research producing these results, primarily studies of Caribbean-born immigrants of high socioeconomic status and educational levels, has not included foreign-born Black women arriving under refugee circumstances. It is unclear whether these more favorable outcomes occur as well in Black refugee populations, which may be more similar in socioeconomic status to US-born Blacks.

To address this question, we compared birth outcomes of Ethiopian-born women delivering infants in Washington State with those of US-born Black and White women. Famine, displacement, and civil war in Ethiopia in the mid-1980s led to greatly increased emigration, and most Ethiopian women in the United States are likely to have arrived recently under refugee circumstances.[6,7]

Methods

Birth certificates for all Washington State singleton births between 1980 and 1991 to Black women born in Ethiopia (n = 264) were obtained and matched in a 1:2 ratio by delivery year to births to randomly selected US-born White (n = 546) and Black (n = 532) Washington women.

Birth certificate data were used to examine demographic differences among these cohorts, and the association between maternal birthplace and infant birthweight was calculated with the Mantel-Haenszel pooled estimator of relative risk (RR) and Greenland/Robins 95% confidence intervals (CIs). Several potential confounders of this association (age, smoking, marital status, parity, prenatal care, and diabetes) were considered, and those variables that altered the relative risk by 10% or greater were included as confounders. US census data were used to calculate family income, defined as the median income of the census tract of residence, for urban residents only.

Results

Births in Washington State to Ethiopian-born women increased from 16 in 1980 through 1982 to 136 in 1989 through 1991. Ethiopian women were older, more likely to be married, less likely to smoke, and less likely to be primiparous than US-born Black and White women (Table 1). The family income of both urban Ethiopians and US-born urban Black women was substantially lower than that of urban White women. Ethiopians and US-born Blacks were less likely than Whites to initiate prenatal care early (Table 2). Gestational diabetes and preeclampsia were more common among Ethiopians than among both US-born groups, while chronic hypertension was less frequent. Anemia during pregnancy occurred among Ethiopian women half as often as among US-born Black women.

Ethiopian-born women were less likely than US-born Blacks to have low-birthweight infants (5.3% vs 7.6%). After adjustment for smoking, marital status, and prenatal care, the relative risk of low birthweight among Ethiopians was similar to that of US-born Blacks (RR = 0.9, 95% CI = 0.5, 1.7) and Whites (RR = 1.1, 95% CI = 0.6, 2.1). Twenty percent of infants born to Ethiopian women weighed 4000 g or more, in comparison with 4% of

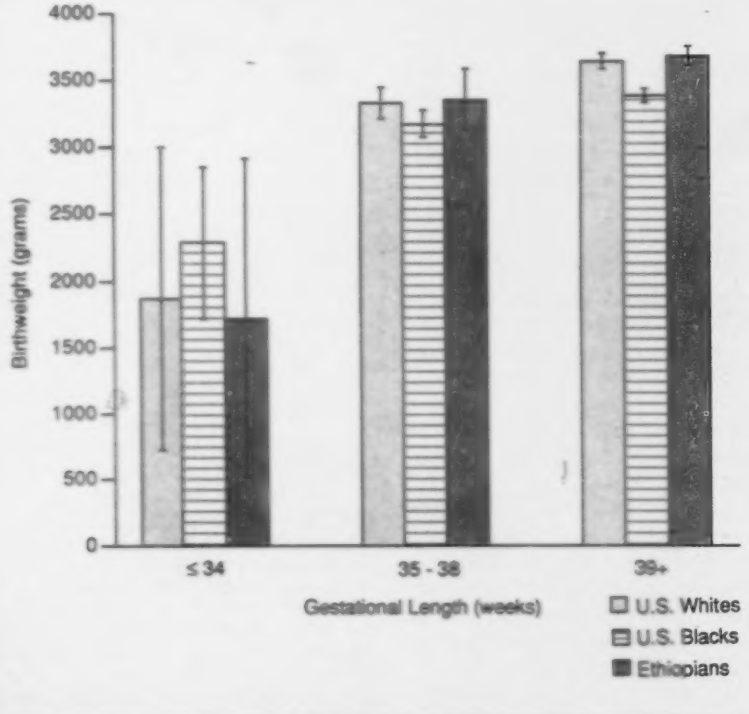

FIGURE 1—Mean birthweights (and 95% confidence intervals), by gestational age and race/ethnicity among nonsmokers.

US-born Black women's infants. After adjustment for smoking, maternal age, and marital status, Ethiopians maintained a significant elevation of macrosomia risk (RR = 4.0, 95% CI = 2.3, 6.8) relative to Black women; however, they evidenced no excess risk (RR = 1.1, 95% CI = 0.8, 1.4) when compared with Whites. Among nonsmokers, Ethiopians had infants of significantly higher mean birthweight than Blacks above 38 weeks gestation ($P < .0001$) (Figure 1).

Discussion

The interpretation of our findings is potentially limited by the absence of detailed socioeconomic information, making it possible that the favorable birth outcomes among Ethiopians in comparison with US-born Blacks were due to socioeconomic advantages. However, reports describing Ethiopian refugees indicate that, unlike the more urban, educated Ethiopians entering the United States in the early 1980s, many of those entering during the mid-1980s and later were illiterate and poor, had little formal education or skills, and were from rural areas.[7,8] The dramatic increase in Washington State deliveries among Ethiopians during the mid- and late 1980s, when a large population of Ethiopian refugees was displaced and left Ethiopia, suggests that many, if not most, of the Ethiopian women in our study were refugees.[9,10] In addition, we found that family income, measured by median income of census tract of residence, was similar among Ethiopians and US-born Blacks, making it unlikely that Ethiopians were an advantaged group.

That Ethiopian women had no greater risk of delivering low-birthweight infants than US-born Whites is surprising in light of their lack of prenatal care and the difficulties they may face upon entering the country. Even more surprising, however, is that 20% of Ethiopian women delivered infants weighing more than 4000 g. The high proportion of large infants born to Ethiopians in comparison with US-born Blacks was not associated with differences in parity, gestational age, or gestational diabetes. Furthermore, among term deliveries, the mean birthweight of Ethiopians was more similar to that of US-born Whites than to that of US-born Blacks. The higher apparent mean birthweight among Blacks at less than 35 weeks gestation shown in Figure 1

was due to a large number of Black births near the upper age limit of this category.

The favorable pregnancy outcomes of Ethiopian women relative to US-born Blacks may be due to several factors. The US-born Black and Ethiopian populations may differ in their responses to physical and emotional stress, and pregnant Ethiopian women may receive more psychological and emotional support than US-born Black women. Hispanic women in the United States have been shown to have pregnancy outcomes more like those of Whites than those of Blacks, attributed in part to supportive communities that may help buffer psychological stress and deter harmful behavioral practices such as smoking and alcohol and drug use.[11] This mechanism may be operating in the Ethiopian community as well, as evidenced by the high marriage and low smoking rates among our Ethiopian subjects. There may also be nutritional differences between Ethiopian and US-born Black women before and during pregnancy. This hypothesis is also supported by our data: the frequency of anemia during pregnancy among Ethiopians was half that of US-born Black women. Finally, genetic differences between Ethiopians and more ethnically heterogeneous US-born Black women may account for some of the difference in birthweight distributions.

Future investigation of the Ethiopian community structure, as well as dietetic and behavioral practices during pregnancy, is warranted to illuminate the reasons for the favorable pregnancy outcomes of Ethiopian women. Such research will promote identification of additional modifiable factors applicable to decreasing low birthweight rates among US-born Black women. □

The Risk of Pregnancy-Induced Hypertension: Black and White Differences in a Military Population

Debra E. Irwin, PhD, David A. Savitz, PhD, Irva Hertz-Picciotto, PhD, and Kenneth A. St. André, MD, MPH

ABSTRACT

The relationship between race and risk of pregnancy-induced hypertension was investigated in a cohort of active-duty military women who gave birth during the period 1987 through 1989. Cases were identified through hospital discharge diagnoses and included transient gestational hypertension, pre-eclampsia, eclampsia, and unspecified hypertension complicating pregnancy. Multivariate analysis showed nulliparous Black women to be at a slightly increased risk for all pregnancy-induced hypertension (risk ratio [RR] = 1.2) and for pre-eclampsia (RR = 1.3) compared with nulliparous White women. Black parous women were found to have a slightly reduced risk of all pregnancy-induced hypertension (RR = 0.77) and pre-eclampsia (RR = 0.38) compared with White parous women. (*Am J Public Health.* 1994;84:1508–1510)

Introduction

Fetal death, low birthweight, and neonatal mortality rates for Blacks are about twice as high as those for Whites,[1] owing in part to inadequate access to gynecological and prenatal services and to life-style factors associated with low socioeconomic status.[1] Some studies report a higher incidence of pregnancy-induced hypertension among Black women than among White women,[2–4] possibly owing to a predominance of socioeconomic and life-style factors potentially related to the disease and to a higher prevalence of undiagnosed preexisting hypertension. Other studies have not found an increased risk among Blacks.[5–8] The present cohort study examines the relationship between race and risk for pregnancy-induced hypertension among active-duty women in the US Navy and Marine Corps, among whom the health, education, and socioeconomic differences between Black and White populations are significantly reduced and the barriers to medical care have been minimized.

Methods

All active-duty US Navy and Marine Corps personnel who were admitted to all military hospitals for a singleton infant delivery between October 1, 1987, and September 30, 1989, were initially included in the cohort (n = 8375). After those with preexisting hypertension recorded at hospital discharge (82 Whites, 24 Blacks, 10 of other races) were excluded, a total of 8259 women were eligible for the study.

Individual hospital discharge records were obtained from the Retrospective Case-Mix Analysis System, a component database of the Defense Medical Information System, which contains hospital discharge summary data for all hospitalizations from Department of Defense–operated hospitals. Women identified in the cohort were linked on social security number to demographic database files at the Defense Manpower Data Center. More than 89% (n = 7364) of the women who were admitted for infant delivery between the stipulated dates were successfully linked. Women who were and were not linked did not differ with respect to age, rank, branch of service, parity, type of delivery, and pregnancy-induced hypertension status. The 377 women who were neither Black nor White were excluded, leaving 6987 women in the analysis.

Women were classified as having pregnancy-induced hypertension if one of their hospital discharge diagnoses was for that disease as defined by the *International Classification of Diseases,* ninth revision (ICD-9)[9]: transient gestational hypertension (code 642.3), pre-eclampsia (642.4 and 642.5), and all pregnancy-induced hypertension (included codes for transient gestational hypertension, pre-eclampsia, eclampsia [642.6], and unspecified hypertension complicating pregnancy [642.9]). Women whose discharge diagnosis indicated infant delivery but did not indicate any of the above pregnancy-induced hypertension diagnoses were considered nondiseased. Crude risks and risk ratios (RRs) were calculated, and adjusted odds ratios (ORs) were obtained by multivariate logistic regression.[10]

Results

Comparison of the sociodemographic and reproductive characteristics of Blacks and Whites in this study indicates that White women were notably more likely than Black women to be married (75% vs 56%) and slightly more likely to be among the officer ranks (9% vs 2%), to be over age 35 (3.4% vs 1.6%), and to have

education past high school (21% vs 17%). Equal proportions of Whites and Blacks were nulliparas, and the proportions diagnosed with pregnancy-induced hypertension were similar. Nulliparas were at increased risk of all pregnancy-induced hypertension (RR = 2.2; 95% confidence interval [CI] = 1.8, 2.7), transient gestational hypertension (RR = 2.0; 95% CI = 1.5, 2.7), and pre-eclampsia (RR = 2.8; 95% CI = 2.0, 3.9) compared with parous women, but there was little association between age, race, marital status, or educational level and risk of these three conditions.

Nulliparous Black women had modestly increased risk ratios for all pregnancy-induced hypertension and pre-eclampsia but not for transient gestational hypertension (Table 1). Among parous women, Blacks were at reduced risk for pre-eclampsia compared with Whites, although both races appear to be at equal risk for the development of all pregnancy-induced hypertension and transient gestational hypertension (Table 2).

Discussion

The current study found a slightly increased risk for pre-eclampsia among nulliparous Black women compared with nulliparous White women in contrast to a fairly strong inverse association for pre-eclampsia among parous Black women compared with parous White women. Eskenazi et al.[2] found nulliparous Blacks to have a dramatically increased risk for pre-eclampsia compared with their White counterparts (OR = 12.3; 95% CI = 1.6, 100.8), whereas parous Blacks were found to have a reduced risk for pre-eclampsia compared with parous Whites (OR = 0.68; 95% CI = 0.13, 3.5). The current study's findings for nulliparous and parous Black women are in the same direction but of different magnitude than Eskenazi et al.'s[2] results. Other studies have reported conflicting findings.[7]

Evaluation of these data requires consideration of the accuracy of the diagnoses recorded in the database. As a regular part of the hospital quality assurance process, the military services have instituted the Civilian External Peer Review program, in which nonmilitary physicians evaluate the accuracy of patient care and diagnoses. This survey showed that inpatient hospital care for pre-eclampsia was found to be more than 97% compliant with diagnostic and case management criteria,[11] limited to evidence concerning false-positive diagnosis but not false-negative diagnosis.

The unique nature of the active-duty military population reduces some of the differences in nutrition, physical activity, and quality of health care that may have affected racial comparisons in previous studies. The preenlistment experiences of Black and White women undoubtedly differ, but at least for their time in the military, racial groups are constrained to be more similar than they would be as civilians: eligibility requirements for enlistment include a high school education or its equivalent; physical standards for initial enlistment prevent individuals with any significant chronic illness or disability from entering on active duty; all candi-

dates for active duty are tested for evidence of illicit drug use on induction into the military and periodically thereafter; and twice each year, individuals must successfully pass a physical fitness test that includes a test of aerobic capacity, flexibility, strength, and body fat content. These standards produce a relatively homogeneous active-duty population that is moderately well educated, physically fit, and essentially disease free. Medical care for preventive and therapeutic services is free of charge and readily available to active-duty personnel. Time for prenatal medical examinations is provided as part of normal working hours, and women are strongly encouraged to obtain early and consistent prenatal care. The selectivity of this population is evident in its lower rates of low birthweight risk (Blacks 6%, Whites 4%) and reduced racial differences in low birthweight risk compared with the general US population (Blacks 13%, Whites 6%).[1]

It is possible that the similar rates of pregnancy-induced hypertension between the racial subgroups and the decreased risks of pre-eclampsia for multiparous Black women found in this study are due to unmeasured confounders. For example, smoking is a strong protective factor for pregnancy-induced hypertension that was not available for analysis and thus was not controlled. A similar study among pregnant women in the military found minimal differences in smoking rates between Blacks and Whites (18% vs 20% smokers) (unpublished data). An alternative explanation for the results found for multiparous women may be differences in the characteristics of Blacks and Whites who stay in the military after giving birth to their first child.

This study suggests that previously reported elevated risks of pregnancy-induced hypertension in Black as compared with White women may be partially explained by poor access to medical care or by a higher prevalence of chronic disease and generally poorer physical fitness. The apparent interaction between race and parity in the etiology of pre-eclampsia warrants further evaluation. Although the stringent selection criteria for entry into the military limits the generalizability of these results, active-duty military personnel serve as a useful population for examining the risks of adverse pregnancy outcome without the potential biasing effects of differential access to medical care. □

Nonclient Factors in the Reporting of Prenatal Psychosocial Risk Assessments

Deborah Schild Wilkinson, MSW, MPH, Carol C. Korenbrot, PhD, and Elena Fuentes-Afflick, MD, MPH

ABSTRACT

Psychosocial and nutrition risk assessments at 27 randomly selected sites of a Medicaid-funded enhanced prenatal program were examined for completeness and uniformity of reporting. The recording of psychosocial data, but not of nutrition data, was found to be associated with a substantial number of nonclient factors, including geographical location and abstractor, assessor, and service provider characteristics. The variability in recording of psychosocial problems reflects the numerous ways that assessments are performed and the subsequent difficulty in interpreting the practice of psychosocial assessment. A uniform system of defining and classifying risks is needed to improve both service delivery and service evaluation. (*Am J Public Health.* 1994;84:1511–1514)

Introduction

Psychosocial services are a growing part of the content of prenatal care for low-income women.[1] The Comprehensive Perinatal Services Program of the California Department of Health Services provides such enhanced prenatal and postnatal care services to Medicaid-eligible pregnant women. As the first step of an attempt to evaluate the associations of psychosocial services with outcomes for women in the program, we investigated whether the documentation of the assessment of five psychosocial problems and one strength was complete and uniform. We identified several nonclient factors associated with the recording of psychosocial risks that were not found in the recording of nutrition risks of the same women. We then examined how the association of reporting of each problem and strength with its region was changed by adjusting for three nonclient factors. The findings have important implications for psychosocial assessment and practice and for the evaluation of their impact on health outcomes.

Methods

The study sample, drawn from a stratified random sample of Comprehensive Perinatal Services Program providers (n = 27) certified by the state Department of Health Services, consisted of 3459 Medicaid-eligible women giving birth from July 1989 to December 1990 (C. Korenbrot et al., unpublished data, 1994).[2] Selection of the sites had been stratified for two metropolitan (Los Angeles and the San Francisco Bay Area) and two nonmetropolitan (Sacramento and areas surrounding Fresno) regions of the state.

Potential psychosocial and nutrition risks were assessed by site personnel who conducted interviews with each pregnant woman. Assessment information was documented on site-specific, state-approved forms.

Any health professional at a Comprehensive Perinatal Services Program site may provide any or all of the support services. A generalist position called "comprehensive perinatal health worker" was created for the program. Such a worker must be more than 18 years of age, have a high school diploma or its equivalent, and have at least 1 year of full-time paid practical experience providing services in a perinatal setting. For this study, the psychosocial assessors were grouped into five categories: social workers (BSW, MSW), nurses (LVN, RN, BSN, PHN, FNP), those with other bachelor's degrees, those with other master's degrees, and comprehensive perinatal health workers. There were four groups of nutrition assessors: registered dietitians, nurses, those with other degrees, and comprehensive perinatal health workers.

Five abstractors were accredited records technicians who collected the data from all but one site. A sixth abstractor, a social worker, collected the data from one site only. Charts from each site were abstracted by only one abstractor. Abstractor training took place in two daylong sessions that included having all technicians abstract the same chart at the end of each session. The procedure was repeated three times during the data collection period to ensure continued reliability. Differences in abstraction of particular items were noted, and feedback was given individually and in group meetings to remove the differences. All abstractors were in continual telephone contact with a single project director who resolved difficulties that occurred with abstracting

Supportive partner	66.9	75.9[a]
Unplanned pregnancy	35.3	57.9[a]
Financial problems	58.4	68.7[a]
Parenting problems	18.9	46.9[a]
Psychological problems	33.2	46.2[a]

[a]Significantly different at the $P < .0001$ level.

data for individual cases. One abstractor was noted to record data in more detail than the others, including margin notes. That abstractor was cautioned against inferring data from the chart notes.

To abstract the psychosocial data as uniformly as possible from the 18 assessment forms used at the 27 sites, a list was compiled associating 122 different phrases used on the forms with 72 different codes. The codes were combined into 27 theoretically consistent risks, each composed of one or more of the codes. Each code was used in only one risk. The risks were constructed as dichotomous variables such that if one or more of the codes was present, the value was 1; otherwise, the value was 0. Five problem areas were included in the analysis: (1) lack of social support, (2) unplanned pregnancy, (3) financial problems, (4) potential and existing parenting problems, and (5) psychological problems. Unplanned pregnancy was composed of a single code, while other risks had several. Lack of social support, for example, had four codes composed of six specific phrases: minimal or no emotional support; lacks social contacts; feels alone or lonely; lives alone (as a risk); multiple partners, numerous unstable relationships; and other social support problems. Other psychosocial data concerning client strengths were collected. One strength (support from husband or partner and/or father of baby) was included in the analysis.

Nine nutrition risks could be coded on the abstraction forms if noted by an assessor in the chart: (1) anemia, (2) chronic disease, (3) eating disorder, (4) high weight gain, (5) low weight gain, (6) inadequate diet, (7) obese before pregnancy, (8) short pregnancy interval, and (9) underweight before pregnancy.

Correlations between the psychosocial and nutrition risks and each of the reporting variables—metropolitan or nonmetropolitan area, data abstractor, educational credential of the risk assessor, and provider type—were measured. Forced hierarchical multiple logistic regression models were then constructed for each dependent psychosocial variable. In the first model, population density (nonmetropolitan) was the sole explanatory variable. In the second hierarchy step, the changes in log-likelihood relative to the first model of models adding only abstractor, assessor's credentials, or provider type were examined; the model with the largest change (abstractor) was selected to be the base of the following models to which each of the two remaining variable groups were added in turn. The final model included all of the variable groups.

Results

Women in the metropolitan areas of the study were unexpectedly found to be significantly less likely to have psychosocial risks than women in nonmetropolitan areas ($P < .0001$; Table 1). We examined the correlation of nonclient factors with the reporting of these psychosocial risks (Table 2) and examined similar correlations for nutrition risks (Table 3). The relative size and significance of the unadjusted correlation of each of the nonclient factors were greater for psychosocial risks (Table 2) than for nutrition risks (Table 3). Thirty-three percent of the correlations for psychosocial risks were greater in magnitude than .10 and were significant at the $P < .001$ level. In contrast, only 10% of the correlations for nutrition risks reached .10, and nearly half of these high correlations involved a single risk: inadequate diet.

Adjustment for abstractor alone removed the association with region for the two support variables (Table 4). Adjustment for all three explanatory variables removed the association of unplanned pregnancy with region. Adjustment for nonclient factors reversed the regional effect for financial problems, resulting in the finding that women in metropolitan regions were more likely, not less likely, to have financial problems. Finally, for two psychosocial risks, potential or existing parenting problems and psychological problems, the regional effect remained regardless of the adjustment model used.

Discussion

In its guidelines for prenatal care, the Public Health Service's Expert Panel[1] has set out a challenge to include in prenatal care a new emphasis on the psychosocial dimensions of care. However, evidence that psychosocial services in practice are associated with the improved health and well-being of pregnant women needs further documentation.[3] The findings of our study demonstrate how the lack of a uniform method of defining and classifying problems makes it impossible to evaluate appropriately the associated impact of psychosocial services in practice. If client problems cannot be systematically classified, then reductions in problems and associated changes in health status for women with problems who receive interventions cannot be evaluated.

Any classification system for psychosocial risks in health care settings must have clear, consistent phraseology and address both the objective and subjective factors related to the problems.[3-8] The system must be practical for use in the field and lead to appropriate interventions as well, and it must be flexible enough to accommodate the cultural differences between populations served. The use of commonly endorsed systems makes the effectiveness of psychosocial services testable. □

The *American Journal of Public Health* (*AJPH*), published monthly, is the official Journal of the American Public Health Association, Inc, 1015 15th St, NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50 000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Mervyn Susser, DPH, Editor, *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005.

Information on Manuscript Preparation is published monthly in the Journal. The Journal publishes reports of original research, research methods, program evaluations, analytic reviews, including health policy analysis, and reports for special departments. A paper is considered with the understanding that it or its essential substance neither has been published nor is under consideration elsewhere.

Subscription price, individual, is $100/year US, $140/year international; **institutional,** $160/year US, $200/year international. Single copies $13 US, $14 international (surface delivery), $22 international (air delivery). Prepaid only.

Postal Information: Second class postage paid at Washington, DC, and additional mailing offices. Postmaster: Send address changes to *American Journal of Public Health*, 1015 15th St, NW, Washington, DC 20005. *AJPH* allotted $40; *The Nation's Health* allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact Director, Membership Services, at APHA headquarters. Printed in the United States.

Advertising Sales: Maureen Sheridan, Advertising Manager, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5668 or 5600. Advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on the first page of published article. For cost information on 100 or more reprints, contact Marilyn Butler, *AJPH* Reprints, APHA, 1015 15th St, NW, Washington, DC 20005; (202) 789-5649.

Back Issues of the Journal: A limited inventory of back issues and volumes of the Journal is available at current subscription rates plus handling charge. All orders under $35 must be prepaid. Vols 1 to present are also available on microfilm.

Changes in Positions of Authority Held by US Physicians: A Fresh Look at Existing Data

ABSTRACT

Some experts contend that physicians have lost positions of authority in the past 40 years. Others argue the opposite, yet neither side bases its arguments on empirical data. This study examined longitudinal variables measuring authority positions held by physicians. Data on the relative position of physicians in medical schools show that medical doctors held 65.6% of the sampled positions in 1970 vs 72.8% in 1990. Yet, in the wider society and within the nonmedical school portion of the health sector, other data indicate that physicians occupy a smaller proportion of authority positions. (*Am J Public Health.* 1994;84:1573–1575)

J. Scott Osberg, PhD

Introduction

Data on positions of authority held by US physicians are widely available, but researchers have not systematically analyzed them. This paper synthesizes existing data on physicians' positions of authority to understand changes over time.

Some experts claim that physicians remain solely in charge of the key health care decisions, including prescriptions for medications, hospital admissions and discharges, and recommendations for surgery.[1] Other experts argue that physicians have lost their dominant position.[2–5] Still others say that physicians are in danger of becoming alienated workers.[6,7] Although many experts do believe that physician authority has declined in the past 40 years,[5,8–10] strong empirical evidence has not been presented.

Methods

Data from the American Association of Medical Colleges for both 1969 to 1970 and 1989 to 1990 were compared to determine if the representation of medical doctors within US medical schools has changed over time.[11,12] In 1969 to 1970, there were 117 schools listed in the Association's directory, compared with 144 in 1989 to 1990. A sample of 62 medical schools in the latter period was randomly selected, and data were collected on the proportion of personnel with medical or other degrees. Identical data were collected on the subset of 45 schools that were listed in the 1969–1970 directory.

Another measure of physician authority can be taken in various health associations. The highest degrees (MD or other) held by presidents of the American Public Health Association (APHA), the American Hospital Association, the American Physical Therapy Association, and the American Nursing Association were examined over time to determine changes in physician representation.[13–15] Data on the number of hospital physician managers and chief executive officers for selected years since 1952 were also considered. Because data were found in two separate sources and the variables were defined differently, comparisons had to be made carefully.[16,17]

The only measure of authority positions held by physicians in the wider society involves physician members of the US Congress.[18,19] There are 535 members of the House and Senate; thus, over any 10-year period, the total member-years served is 5350.

Results and Discussion

Table 1 shows that, overall in 1970, 65.6% of the sample of "key personnel" listed in the American Association of Medical Colleges directory held medical doctorates versus 72.8% in 1990. This evidence suggests that physicians have gained positions of authority in medical schools, at least over the past 20 years.

The American Medical Association has always been headed by a physician. In contrast, the American Physical Therapy Association and the American Nursing Association have never been headed by physicians. None of the 20 presidents of the American Hospital Association from 1970 to 1989 was a medical doctor, in contrast to 1930 to 1969, when 22 of 40 (55%) were physicians (Table 2). With

TABLE 2—Presidents of the American Public Health Association (APHA) and the American Hospital Association (AHA) and Physician Years in the US Congress, by Decade

	1900s	1910s	1920s	1930s	1940s	1950s	1960s	1970s	1980s
Percentage of physician presidents of AHA	---	---	---	70	50	40	60	0	0
Percentage of physician presidents of APHA	---	---	---	80	100	70	70	60	30
Physician-years in the US Congress	71	59	88	82	74	51	39	47	50

Note. The highest degree (MD or other) of presidents of AHA and APHA were collected over time (1 = MD, 0 = other). Data were taken from the *American Hospital Association Guide to the Health Care Field, 1987 Edition*,[13] Appendix D4, for 1929 to 1986; from recent years in *Hospitals*[14]; and from issues of *American Journal of Public Health*.[15] Data for physician-years in Congress from 1900 to 1959 were found in Burrow[18]; data for 1960 to 1989 were found in *Vital Statistics on Congress*.[19]

respect to the APHA, the change in physician domination has been less drastic. During the period from 1930 to 1969, 32 of 40 APHA presidents were medical doctors (80%), compared with only 9 of 20 (45%) from 1970 to 1989.

Physicians no longer dominate *the presidency* of APHA, yet other ungraphed results show that they still have a strong presence in the organization. In 1987, 50% of the 16-member executive board held medical degrees, and except for the president, who had a law degree, all six APHA officers held medical doctorates.

Although a physician has never headed the American Nursing Association, nursing is one area over which physicians have lost much control. Where nurses were once considered the physicians' "handmaidens," nursing now is a separate field with its own clearly demarcated lines of authority.[20]

The American Physical Therapy Association also has never had a physician as its president (personal communication with association staff, December 1991). However, the association was subservient to medicine, as seen in its mission statement in the 1937 Constitution: "To cooperate with, and to work only under the prescription of members of the medical profession."[21(p2)] In its early years, when it was called the American Women's Physical Therapy Association, it did have an advisory council comprised entirely of medical doctors.[22] However, this council was disbanded in 1968, and physicians no longer have a formal role in the association. In addition, in 1973 the association voted to bypass the need for physician referral.[23] The cumulative effect of all these changes indicates a loss of physician authority over physical therapy.[24]

There was a 13.5% decline in physician administrators, from 1851 in 1952 to 1602 in 1962.[17] According to Katzive, the heyday of medical administrators was in the early 1950s, with physician administrators representing 32.5% of all hospital administrators.[17] In contrast, 25.0% of administrators were physicians in 1945, and by 1962, although the number of hospital administrators grew, the percentage of physician administrators dropped to 22.8%. During the 10-year span beginning in 1972, the number of chief executive officers who were physicians declined by 75%, from 813 to 202.[16]

The trend away from physician administrators and hospital chief executive officers with medical degrees supports the large body of literature that has noted the rise of the hospital administrator and the decline of the physician administrator.[3,25–27] But is the flip side of administrators' rise the physicians' decline? As Freidson points out, even though nonphysician administrators hold many of the top posts, they are in many ways still beholden to the medical staff.[28] It could be that the rise of the hospital administrator is more properly considered a sign of a larger trend toward specialization,[29,30] and not a sign of an onslaught against physicians or of physician decline.

Table 2 shows physician membership in the US Congress in this century. In the 1920s, at the peak of physician membership, physicians constituted only 1.6% of the membership (88 of 5350 years). At the lowest point, in the 1960s, congressional membership comprised 0.7% physicians. Physicians may be less involved as national office holders, but perhaps Altman is right in noting that physicians today are more involved at the state and local level than they were in the past.[31]

Although today physicians make up a smaller proportion of Congress, they still have a great deal of influence over that body; US politicians have long been reluctant to offend the medical profession by seriously challenging physician authority.[32] In the first 18 months of the 1990 election cycle, the American Medical Association gave $2.1 million to congressional candidates.[33] It remains to be seen how physicians will use their political clout to shape President Clinton's proposed Health Security Act. Will Congress be able to resist the lobbying of physicians, hospitals, insurance companies, and pharmaceutical companies and pass meaningful reform?

These data reveal some losses in authority positions held by physicians over the past several decades; yet in medical schools, a remaining bastion of medical power, physicians seem to have solidified and expanded their hegemony. Further analysis of similar longitudinal data is needed, along with other research showing the extent to which physicians are pulling the strings behind the scenes from powerful, but less conspicuous, positions. □

Estimates of Population Smoking Prevalence: Self- vs Proxy Reports of Smoking Status

Elizabeth A. Gilpin, MS, John P. Pierce, PhD, Shirley W. Cavin, MS, Charles C. Berry, PhD, Nicola J. Evans, PhD, Michael Johnson, PhD, and Dileep G. Bal, MD

ABSTRACT

Objectives. In the face of rising costs of surveillance systems, it is time to reexamine the feasibility of including proxy respondents in surveys designed to provide population estimates of smoking prevalence.

Methods. Data are from the California Tobacco Surveys, which are random-digit dialed telephone surveys. One adult provided demographic information and smoking status for all household residents. Additionally, some adults were selected for in-depth interviews that also included smoking status questions. We matched information from proxy respondents and self-respondents and evaluated smoking status discrepancies between them relative to demographic and other factors (n = 2930 matched pairs) in 1992. We address the potential bias these discrepancies might introduce into the population estimate of smoking prevalence.

Results. Overall, the discrepancy between proxy report and self-report was 4.3%, and it increased particularly when the self-respondent reported nondaily smoking or recent quitting. Discrepancies acted in both directions, and the net bias was that the screener survey overestimated smoking prevalence by 0.1% in 1992 (0.3% in 1990).

Conclusions. Smoking status questions can be added to ongoing surveys such as the census or labor force surveys; one adult could provide smoking status for all household members. (*Am J Public Health.* 1994; 84:1576–1579)

Introduction

Cigarette smoking has been identified as one of the most preventable causes of death and disability.[1,2] Accordingly, a surveillance system for smoking prevalence is important for many public health authorities at the state level. Establishing such a surveillance system requires addressing the issues of validity and cost.

The primary survey used to track smoking prevalence in the United States has been the National Health Interview Survey (NHIS).[2–4] Because the NHIS design provides population estimates representative of four regions of the continental United States, it cannot provide reliable state-specific estimates of smoking prevalence. In 1974 the NHIS decided to collect data on smoking status only from self-respondents.[5] Given that other types of surveys use proxy respondents, it is timely to consider the impact of including proxy respondents in the overall estimate of smoking prevalence.

Cost can be minimized if the proposed surveillance system can be incorporated into ongoing surveys, such as the population census or labor force participation surveys. In the United States, the Bureau of the Census conducts the Current Population Survey, which serves as the vehicle for evaluating state-level interventions in the large-scale American Stop Smoking Intervention Study project (ASSIST), which is a joint effort of the National Cancer Institute and the American Cancer Society.[6] These surveys typically seek information on all household members from one respondent; that is, they include information from a proxy respondent. Most households in the United States include two or more adults, and the second adult usually represents either a different sex or a different age group. In surveys that have sought to interview these other adults, the drop in response rate was considerable.[7] Thus, surveys that include information from proxy respondents may lead to more representative population estimates achieved with minimal statistical adjustment. Also, the sample size is increased considerably for only a marginal increase in the cost of a single interview. This advantage becomes particularly important when the survey is to be used to estimate smoking prevalence in demographic subgroups.

In the California Tobacco Surveys, one adult reported on his or her own smoking status and acted as a proxy respondent for other adults in the household. In addition, a subsequent in-depth survey of tobacco use was undertaken in some adults who had their smoking status previously reported by proxy on the screener survey.

This study examines the extent of discrepancies in current smoking status between the proxy–self pairs and explores demographic and other factors that might be associated with higher discrepancy levels. In addition, we computed adjusted estimates of smoking prevalence based on the observed discrepancy levels so that the

degree of bias attributable to the inclusion of proxy responses could be determined.

Methods

Surveys

The California Tobacco Surveys are population-based, random-digit dialed telephone surveys.[8,9] In each household (n = 10 774 in 1992), an adult was administered a screener questionnaire that collected basic demographic information, including smoking status, for each household member. Each person enumerated (n = 21 870) was given a weight so that population-based estimates could be computed.[9] Briefly, the base weight reflects the probability that the household was selected, and it is adjusted to ensure that the sample is representative of the California population with respect to age, sex, county/region, education, and race/ethnicity.

From the information enumerated on the screener interview, some adults (≥ 18 years) were selected for in-depth interviews. All persons who had smoked in the last 5 years were selected, as were a random sample of 28% of those who had not (total n = 7263). A weighting procedure similar to that used for the screener respondents was also applied to the respondents who had the in-depth interview; it further adjusted for the fact that proportionately more smokers or persons who had quit smoking in the last 5 years than nonsmokers were interviewed in depth.[9] With this survey design, some individuals had smoking status reported both by proxy from the screener respondent and by self from the in-depth interview (n = 2930). It should be noted that 51.3% of the persons enumerated on the screener interview provided their own smoking status. In the analysis that examines the factors related to discrepancies (described below), the respondent weights from the in-depth interview are used.

Smoking Status

In the screener interview, the respondent was asked, "[As far as you know], have you [has person] smoked at least 100 cigarettes during your [his/her] lifetime?" If the answer to this question was "yes," the respondent was asked, "Do you [does person] smoke cigarettes now?" If the answer to this questions was "no," the respondent was asked, "Have you [has person] quit smoking during the past 5 years, [as far as you know]?"

In the in-depth interview, each respondent was asked the same set of questions. Those who had smoked 100 cigarettes and who were not smoking when surveyed were asked the date when they last smoked. In addition, current smokers were asked, "On how many days in the last month did you smoke?" Those smoking 25 or fewer days in the last month were considered occasional rather than daily smokers.[10] All persons who had smoked in the last year were asked the date and length of any quit attempts during the last year.

TABLE 1—Proxy-Reported Smoking Status for Each Group of Self-Reported Smoking Status

Smoking Status: Proxy Report	Smoking Status: Self-Report, No. (%)				
	Current Daily	Current Occasional	Quit Less than 1 Year Ago	Other[a]	Total
Current	911 (96.3)	154 (65.3)	46 (26.4)	59 (1.6)	1170
Quit less than 5 years ago	13 (1.2)	29 (10.5)	100 (49.6)	388 (19.2)	530
Other[a]	8 (2.5)	20 (24.2)	14 (24.0)	1188 (79.2)	1230
Total	932	203	160	1635	2930

Note. Percentages are weighted with in-depth interview weights (see Methods section).
[a]Other includes never smokers and longer-term former smokers.

Analytical Methods

Proxy–self pair discrepancies. For each category of self-reported smoking status (current daily, current occasional, quit in last year, nonsmoker for at least 1 year), we computed the weighted percentages of proxies reporting current smoking, quit in last 5 years, and nonsmoker for at least 5 years. A logistic regression of the likelihood of discrepancy was conducted to determine whether factors that appeared related to an increased discrepancy rate were independently related after controlling for all the other factors.[11] Because of the complex survey design, a jackknife resampling procedure was used to obtain variance estimates for the regression coefficients so that the independent significance of each variable could be assessed.[9]

Effect of proxy errors on estimate of smoking prevalence. To calculate the impact of discrepancies on the overall estimate of smoking prevalence, we estimated discrepancy percentages for each smoking status group that could be determined from the screener data: proxy-reported current smokers who self-reported nonsmoking (D1), proxy-reported quitters in the last 5 years who self-reported current smoking (D2), proxy-reported former smokers for at least 5 years who self-reported current smoking (D3), and proxy-reported never smokers who self-reported current smoking (D4). In order to obtain estimates that are as accurate as possible, data from the 1990 California Tobacco Surveys were pooled with the 1992 data to estimate these discrepancy rates. (The 1990 California Tobacco Surveys surveyed 32 125 households with 65 139 adults enumerated. A total of 24 296 adults received the extended interview, yielding 9384 self–proxy pairs. The 1990 survey did not ascertain the relationship of the self- and proxy respondents, so this paper reports mainly the 1992 results.) Screener weights for the discrepant pairs were summed across surveys and divided by the sum of the sums of weights for the two surveys.

The estimate of smoking prevalence from the screener survey was computed as follows:

$$p = \sum_{i=1}^{K} w_i \cdot s_i / \sum_{i=1}^{K} w_i$$

where $s_i = 1$ if the respondent is a current smoker and 0 otherwise, and w_i is the weight for a person enumerated on the screener. K is the total number of adults from the screener interview. The four discrepancy rates estimated from the proxy–self pairs were used to correct the prevalence estimate from the screener survey as follows:

$$p = \left[\sum_{i=1}^{n0} w_i \cdot s_i + (1 - \mathrm{D1}) \cdot \sum_{i=1}^{n1} w_i + \mathrm{D2} \cdot \sum_{i=1}^{n2} w_i + \mathrm{D3} \cdot \sum_{i=1}^{n3} w_i + \mathrm{D4} \cdot \sum_{i=1}^{n4} w_i \right] / \sum_{i=1}^{K} w_i$$

where $n0$ = number of self-respondents on screener (reported own smoking status and served as proxy respondent for other adult household members); $n1$ = number

TABLE 2—Proxy–Self Discrepancies in Subgroups Defined by Various Factors Related to the Household and Proxy and Self-Respondents

of proxy-designated current smokers; $n2$ = number of proxy-designated former smokers within the last 5 years; $n3$ = number of proxy-designated former smokers who quit more than 5 years ago; and $n4$ = number of proxy-designated never smokers. Note that $K = n0 + n1 + n2 + n3 + n4$.

Results

Smoking Status Agreement Among Proxy–Self Pairs

Table 1 shows the number of proxy–self pairs and how they are distributed with respect to agreement and disagreement. The percentages shown are weighted column percentages of the distribution of proxy classification for each category of self-classification. Self-respondent and proxy-respondent reports of current daily smoking agreed in 96.3% of the cases. Percentages for the "Other" possible smoking status classification are also shown. Of particular interest is that proxy respondents classified as current smokers 26.4% of self-reported quitters in the last year.

Factors Related to Proxy–Self Discrepancy

Overall, among the 2930 proxy–self pairs for 1992, there were 175 (4.3%, weighted percentage) discrepancies concerning current smoker or nonsmoker status (Table 2). In 105 of these cases the proxy called a self-reported nonsmoker a current smoker, and in 70 cases the proxy called a self-reported smoker a nonsmoker. When weighted, these two discrepancies represent nearly equal percentages of the proxy–self pairs, 2.1% and 2.2%, respectively. In addition to the overall discrepancy rate for each demographic category, Table 2 shows a P value that was obtained by using specially coded variables contrasting each category to the indicated reference in the logistic regression analysis. This P value indicates the independent significance of a given category after adjusting for all the other variables.

Although there were trends for more discrepancies for younger, male, Hispanic, and less-educated self-respondents, none of these factors was significantly related to the likelihood of discrepancy. Other nonsignificant trends included higher discrepancy rates when the self-respondent and proxy-respondent were unrelated or when the relationship was other than spouse/partner, parent/guardian, or sibling. Also, discrepancy rates increased with larger household size.

The discrepancy rate was not related to the smoking status of the proxy nor to the time elapsed between the screener and in-depth interviews. Some persons selected for an in-depth interview were not available when the screener interview was administered and were contacted later. If over a week elapsed between interviews, the self-respondent's smoking status might change.

When the self-respondent reported quitting in the last year, the discrepancy rate was significantly greater than that in the reference group of those who had not smoked in the last year. Finally, self-respondents who were occasional smokers showed a significantly higher rate of proxy discrepancy.

Effect of Potential Discrepancy on Estimate of California Smoking Prevalence

Smoking prevalence for California estimated from the screener survey was 20.0 ± 0.7% in 1992. The error rates D1, D2, D3, and D4 were estimated to be 12.0%, 7.8%, 1.9%, and 2.4%, respec-

tively. The corrected smoking prevalence estimate with these percentages was 19.9%. Thus, the screener tended to overestimate smoking prevalence by 0.1% in 1992 (0.3% in 1990).

Discussion

The use of proxy respondents in population surveys of smoking status can substantially decrease the cost of obtaining a smoking prevalence estimate with minimal bias caused by potential error on the part of the proxy respondent. Inclusion of proxy respondents led to a more conservative estimate of smoking prevalence compared with the corrected estimates. The survey results are likely to be more representative because the problem of nonresponse of individuals selected for subsequent self-report does not occur. Furthermore, such a cluster sampling approach has been demonstrated to produce unbiased population estimates.[12]

The two types of discrepancies with respect to current smoking status tended to cancel one another; however, the net effect was a slight increase in the estimate of smoking prevalence when proxy respondents were included. As in a previous study,[13] the degree of discrepancy was not great, and it should be remembered that about half of the screener adults were self-respondents. The overall nature of the discrepancies was very similar for both the 1990 and 1992 surveys (Table 1), so if the same type of screener survey instrument is used for surveillance of smoking prevalence, any bias that is introduced should be present to the same degree. Thus, any change in smoking prevalence detected with such an instrument should be unaffected by the bias.

Although the proxy–self discrepancy rate was particularly high in some cases (nondaily smokers and recent quitters), these groups comprise a relatively small fraction of the total adult population. In agreement with a previous study,[13] we found that spouses and children tended to provide more accurate information than other relatives or unrelated individuals. This was expected as the immediate family would typically have a closer relationship with the individual and hence have more complete knowledge of his or her behavior. Hispanics appear to have a higher discrepancy rate than other racial/ethnic groups. Hispanic households are typically large, so household size may have partly accounted for this result. The more likely factor is occasional smoking, which we have previously shown to be particularly high among Hispanic smokers.[7,10]

We assumed that the self-report of smoking status was the correct one; however, it has been demonstrated that around 30% of self-reported quitters who participated in cessation programs have positive biochemical tests indicating that they have recently smoked.[14–16] Some programs validate self-report of recent quitting with the report of a significant other.[17] In our study, 26.4% of self-reported recent quitters were reported by the proxy to be smoking (Table 1). These reporting discrepancies are similar to those identified in clinic programs. Smokers are faced with considerable social pressure to quit, which may lead to a "wish bias" in self-reporting or desire to please the interviewer. Finally, those who are trying to quit or who do not smoke daily simply might not consider themselves smokers although the proxy does.

Although smoking prevalence is usually the most important issue that needs to be addressed in assessing a population's smoking problem, information on initiation, quitting, and relapse patterns is also of interest. Others have shown that proxy respondents can be reliable for current status of health issues,[18] and the screener survey instrument we described appears reliable for estimating smoking prevalence. However, because of concerns about accuracy,[19–23] we did not obtain detailed smoking histories and consumption levels from proxy respondents.

Our results from two large population surveys indicate that the use of proxy reporting of smoking status is cost-effective and minimally biased. Thus, it is recommended that surveillance systems for smoking prevalence use the approach of having one adult report smoking status for all adults in the household. □

Job Strain and Health-Related Quality of Life in a National Sample

Debra J. Lerner, PhD, Sol Levine, PhD, Sue Malspeis, SM, and Ralph B. D'Agostino, PhD

ABSTRACT

Objectives. Studies of the health effects of job strain have focused on morbidity and mortality as outcomes. This is the first study to examine the relationship of job strain to more comprehensive health status measures that encompass health-related quality of life.

Methods. In a national cross-sectional survey, 1319 working men and women, aged 18 through 64 years, completed a modified version of the Job Content Questionnaire that classified workers' jobs into four categories: high strain, passive, low strain, and active. Subjects also completed the Medical Outcomes Study Short-Form Health Survey and a health distress scale. Logistic regression analyses were employed that controlled for age, race/ethnicity, gender, and education. Both work and nonwork variables were included.

Results. Job strain was significantly associated with five of nine components of health-related quality of life: physical functioning, role functioning related to physical health, vitality, social functioning, and mental health. Job strain made a modest yet statistically significant contribution beyond the effects of chronic illness and psychosocial variables.

Conclusions. The results provide justification for further investigating the role of job strain as an independent risk factor for health-related quality of life. (*Am J Public Health.* 1994;84:1580–1585)

Introduction

A large literature on job strain[1] and its psychological and physical sequelae[1–11] has made us aware of the significant influence of the psychosocial work environment on health. According to Karasek and Theörell,[1] job strain and its health effects result from the interaction of two factors: (1) a job's psychological "demands" and (2) the degree of "control" or decision latitude a worker may exert over those demands. Control is, in effect, a modifier of a job's psychological demands.

In mostly cross-sectional and/or retrospective studies, "high-strain" jobs (high demand and low control) have been found to be negatively associated with health. Job strain has been associated with cardiovascular disease, left ventricular hypertrophy, and cardiovascular disease risk factors[2–7,11]; retiree mortality[10]; and sleep problems, depression, and psychosomatic symptoms.[8] Hypertension studies have produced conflicting results.[6,9] The "healthier" jobs have been characterized by low demand and high control (i.e., the "low strain" jobs) or high demand and high control (i.e., the "active" jobs). "Passive" jobs (low demand and low control) fall in between the two health extremes.

Our job-strain study goes beyond the usual morbidity or mortality outcomes by assessing the relationship of job strain to indicators of health-related quality of life. We also expand on health-related quality-of-life studies that focused on the influences of illness and medical care while excluding social variables.

Health-related quality-of-life indicators usually encompass a person's ability to function effectively physically, emotionally, and socially and to maintain a sense of well-being.[12–14] The more traditional biomedical health status measures capture the presence, absence, and/or severity of disease or mortality. Although health-related quality-of-life indicators were developed mainly to reflect the consequences of health problems and related treatments,[13] losses in functional capacity or sense of well-being may conceivably precede, follow, or be independent of disease.

We assessed job strain's contribution to health-related quality of life independently of demographic, medical, and other psychosocial variables; many previous studies did not consider other variables that might modify the job strain–health relationship. We also asked whether family and/or workplace supports buffer health differences attributable to job strain.

Methods

Our nationwide health survey was conducted between October 15 and December 22, 1990, by the National Opinion Research Center. Participants were drawn from the Research Center's own 1989 and 1990 General Social Survey samples. For our survey, the Research Center attempted to reinterview 3251 subjects from 2909 General Social Survey households. The resulting sample consisted of 2474 respondents (total response rate = 77%).

Debra J. Lerner, Sol Levine, and Sue Malspeis are with The Health Institute, New England Medical Center, Boston, Mass. Ralph B. D'Agostino is with the Department of Mathematics, Boston University, Boston, Mass.

This paper was accepted January 25, 1994.

The present analysis was limited to 1319 men and women under 65 years of age who were employed full or part time. Most respondents at least 65 years of age were retired.

Health-Related Quality of Life

Health-related quality of life was measured with the 36-item version of the Medical Outcomes Study Short-Form Health Survey (SF-36).[15] The SF-36 consists of eight subscales measuring aspects of physical, emotional, social, and role functioning; bodily pain; vitality; and general and mental health perceptions. For most items, respondents are asked to evaluate their own health during the past 4 weeks. We also included a health distress scale developed by the same researchers.

The psychometric properties of the SF-36 have been examined extensively and support its validity, reliability, and precision and its advantages over similar instruments in detecting low-level health deficits.[16] It has been shown to distinguish healthy from chronically ill individuals, patients with different types of chronic conditions and degrees of severity, and medically and psychiatrically ill groups.[17–21] The internal-consistency reliability of most of the individual subscales based on the present data was excellent ($\alpha s \geq .76–.93$). However, the social function subscale, which contains only two items, did not perform as well ($\alpha = .62$).

SF-36 scores range from 0 (low) to 100 (high). A maximum score of 100 implies the absence of impairment. Results from the Medical Outcomes Study with the 20-item version of the SF-36 indicate that on the general health perceptions, mental health, or bodily pain subscales, a 3-point difference is sufficient to distinguish non-chronically ill persons from those with some form of chronic illness.[18]

In coding missing items on the SF-36 subscale, we followed the scoring method recommended by Ware and colleagues[22]: substituting the respondent's own mean subscale score for the missing item(s). For all other subscales, we used the more conservative approach of replacing a missing item score with the total sample's mean score for that specific item.

Measurement of the Independent Variables

A modified version of the Job Content Questionnaire[23] assessed job demands and control. (The item list can be obtained from the authors.) The Job Content Questionnaire was derived from the 1969, 1972, and 1977 National Quality of Employment Surveys, and recent analyses have begun to confirm its validity and reliability.[1] Cronbach's alpha statistics for the demand and control subscales used in this study were .71 and .76, respectively. One item in the control subscale, "repetitive work," had an item-to-total Pearson correlation coefficient of .21. ($\alpha = .81$). Principal-components analysis identified three factors. Two were roughly comparable to Karasek's original demand and control subscales. Repetitive work emerged as a third factor, although it contributed more heavily to the control factor. In keeping with Karasek's model, we elected to keep repetitiveness in the control subscale.

We created the four job-strain groups by dividing the distributions of the demand and control dimensions at their respective medians (thereby constructing a high and low group for each dimension) and cross-classifying subjects. Scores located on the demand and/or control medians were classified as "low." Figure 1 shows the resultant four job-strain groups.

We also included the following additional Job Content Questionnaire items:

- A physical demand item.
- Two items measuring support, one each from coworkers and supervisors.
- Single-item measures of perceived job security, skill obsolescence, and future ambiguity (the last three were summed to form an index of job insecurity).

The following additional classes of independent variables were included:

- Demographics.
- Employment status.
- Chronic illness.
- Psychosocial variables (e.g., social supports,[24] life satisfaction).

Descriptive data for these variables are included in Table 1.

Statistical Analysis

We produced descriptive data for the major variables (Table 1), statistical comparisons of health status scores among the job-strain groups (Table 2), and multivariate models depicting the relationship of each of the nine health subscales to the independent variables (Tables 3 and 4). Three dependent variables (vitality, general health perceptions, and mental health) were normally distributed. Consistent with previous studies, the remaining six dependent variables were nonnormal, with the bulk of the responses at 100.[18]

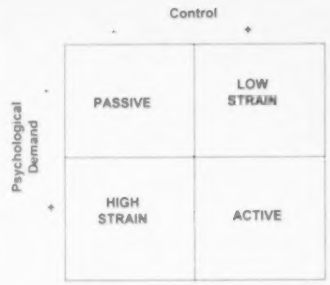

FIGURE 1—Job-strain model.

TABLE 1—Demographic and Psychosocial Characteristics of Study Sample (n = 1319)

Characteristic	Percentage
Female	51.9
White	83.5
Not married	39.7
Full-time job	83.9
Job type	
Manual	22.4
Nonmanual	43.4
Other/sales and service	34.2
No. chronic conditions[a]	
None	34.3
1	25.0
2	19.3
3 or more	21.4
	Mean
Age, y	39.0
Education, y	13.6
General social support (min = 5, max = 25)	18.9
Satisfaction, financial and environmental conditions (min = 4, max = 20)	13.6
Satisfaction, psychosocial conditions (min = 2, max = 10)	7.3
General life satisfaction (min = 1, max = 5)	3.4

Note. Sample includes full-time and part-time employees younger than 65 years of age. No more than 10 responses were missing from any variable.

[a]To create the chronic-condition variable, we combined responses from two questions: whether a doctor had diagnosed any of six specific conditions (yes = 21%) and a self-report of the presence or absence of eight specific conditions and an "other condition" (yes = 61%).

TABLE 2—Mean Health Status Scores, by Job-Strain Group

Health Measures	Job-Strain Groups[a]										
	Passive (n = 430)		Low Strain (n = 303)		High Strain (n = 314)		Active (n = 260)		Total Sample (n = 1307)		US Norm[b]
Physical function[c]	90.0	1.5	92.9	1.5	85.3	2.3	93.0	1.7	90.1	0.9	84.1
Role function/physical[c]	88.8	2.5	90.9	2.6	80.1	3.8	91.7	2.6	87.8	1.5	81.0
Bodily pain[c]	77.0	2.0	81.3	2.2	71.2	2.7	80.8	2.2	77.4	1.2	75.2
General health perceptions[d]	74.4	1.6	79.2	1.8	71.1	2.3	80.2	1.9	75.9	1.0	72.0
Vitality[d]	62.0	1.8	67.6	1.8	54.4	2.5	64.6	2.4	62.0	1.1	60.9
Social function[c]	86.5	1.9	87.6	2.3	79.4	2.6	88.7	2.2	85.5	1.1	83.3
Role function/emotional[c]	84.5	2.3	88.1	2.9	75.6	4.1	86.3	3.4	83.6	1.7	81.3
Mental health[d]	75.5	1.6	79.7	1.7	68.5	2.2	77.2	1.9	75.1	0.9	74.7
Health distress[c]	87.4	1.8	91.0	1.6	81.5	2.7	89.6	2.0	87.3	1.0	85.3

Note. Numbers in columns represent mean and 95% CI (±) with $P < .001$ for all row comparisons.
[a]No more than four responses were missing from any job-strain group.
[b]National norms based on the National Opinion Research Center survey are means weighted to reflect age, sex, and regional distribution of the US population.
[c]Differences tested with Kruskal-Wallis test.
[d]Differences tested with analysis of variance.

Health status differences among the job-strain groups were tested with analysis of variance (ANOVA) for the normally distributed dependent variables. The Kruskal–Wallis test was used for the non-normally distributed health measures (Table 2).

Before final logistic regression analyses were performed, a series of cross-tabulations, correlations, and logistic stepwise regressions were run to clarify the relationships of independent variables within the same conceptual class (e.g., demographic) to the dependent variables. This analysis helped minimize redundancy among conceptually related independent variables. Bivariate correlations (Pearson's Product Moment Correlation) showed total social support to be more strongly related to the dependent variables than either the affective-support or the instrumental-support variable. Marital status did not add significantly to the demographic model but was retained as an independent variable because of its substantive importance. The full set of nonredundant variables was entered into logistic regression models. We culled the statistically significant variables for our final models and identified any variables causing collinearity problems (see Results). Health scores were dichotomized at the median, and we controlled for age, gender, race/ethnicity, and education. Job strain was entered as a four-class dummy variable with the high-strain group always used as the comparison group and coded as zero.

Results are presented in Tables 3 (physical health dimensions) and 4 (emotional health dimensions) as odds ratios and associated significance levels, model chi squares and associated significance levels, and areas under the receiver operating characteristic (ROC) curve. ROC curves plot the relationship between the rate of true-positive classifications to the rate of false-positive classifications.[25] The area under the curve is a goodness-of-fit measure with values above .75 considered acceptable. All models were checked for collinearity problems and none were found.

Results

The demographic characteristics of the sample are described in Table 1.

Work Characteristics

Slightly less than one fourth (23%) of the workers in our sample had high-strain jobs. One third had passive jobs, 24% had low-strain jobs, and one fifth had active jobs.

Almost one fourth (24%) had physically demanding jobs. However, although many described work as psychologically and/or physically demanding, most coworkers (80%) and supervisors (65%) were considered supportive.

Sixteen percent reported job insecurity, and 28% regarded their career prospects as poor. Only 5% predicted their own skill obsolescence.

SF-36 Subscales (Table 2)

Mean SF-36 scores were consistently lowest among workers in the high-strain jobs. The active group and the low-strain group alternated as being the healthiest of the four. The passive group was in the middle.

Health disparities among the job-strain groups were sometimes large. There was a 13.2-point difference in mean vitality scores between the high-strain and low-strain groups and a 12.5-point difference in mean role function/emotional scores (i.e., due to emotional health). All row comparisons with ANOVA or the Kruskal-Wallis test were statistically significant.

Multivariate Results (Tables 3 and 4)

The passive, low-strain, and active job groups each had statistically significant health advantages over the high-strain groups. After the influences of demographics, chronic conditions, and other variables were taken into account, high job strain was significantly associated with lower scores on five subscales: physical function, role function/physical (i.e., due to physical health), vitality, social function, and mental health.

Compared with the high-strain group, the low-strain and passive groups had about 60% to 80% higher odds of experiencing better physical function, role function/physical, social function, and vitality. Vitality levels in the active group also were significantly better than those in the high-strain group. Job strain had its largest impact on mental health; compared with the passive and low-strain groups, the high-strain group had double the odds of poorer mental health.

Note. Models control for continuous age; gender (male = 1, female = 0); race (White = 1, non-White = 0); and continuous education.

[a]Continuous variables and ranges: (1) workplace support (2 to 10); (2) social support (5 to 25); (3) number of chronic conditions (0 to 3 or more); (4) job insecurity (3 to 15); (5) physical job demands (1 to 5); (6) life satisfaction (1 to 5); (7) satisfaction/material (4 to 20); (8) satisfaction/social (2 to 10). Dichotomous variables: (9) job strain, entered as a set of three dummy variables with high strain as the comparison group; (10) 1 = married, 0 = not married; (11) 1 = manual work, 0 = professional, sales, clerical, service work; (12) 1 = nonmanual work, 0 = manual, sales, clerical, service work; (13) 1 = full time, 0 = part time.

*$.01 < P \leq .05$; **$P \leq .001$.

Social Supports (Tables 3 and 4)

The main effects of workplace support were associated with higher odds of freedom from bodily pain as well as improved vitality, and role function, and emotional health. General social support was associated with five of the subscales. However, none of the strain and support interaction terms, which would have suggested a buffering effect, was significant. In early analyses, the interaction term "workplace support by job strain" had a significant negative association with role function/emotional; the high-strain, low-support group had the lowest scores. However, the interaction term was collinear with the main effect of workplace support and was dropped from the model. Collinearity problems caused by the general "social support by job strain" interaction term in the physical-function model led to its elimination.

Other Variables

Two thirds of the sample reported one or more chronic conditions. The number of chronic conditions reported (up to three or more) was strongly associated with all nine subscales. Each unit increase in the number of chronic conditions decreased the odds of good health by one fourth to one half.

Job insecurity and physically demanding work were associated with poorer health in several models. Life satisfaction had a strong, positive association in five of the eight models (mental health was excluded). People who reported high satisfaction were twice as likely to have good vitality, social function, and role function/emotional.

Satisfaction with environmental and financial circumstances (e.g., housing, standard of living) and satisfaction with family and friends were linked significantly with health in several of the models.

Discussion

Job strain was associated with five components of health-related quality of life: physical functioning, role functioning related to physical health, vitality, social functioning, and mental health. Some health differences, such as those contained in the mental health model, were substantial. In contrast, job strain was associated only marginally with physical functioning ($P \geq .051$).

Although the results support our main hypotheses, we were limited by cross-sectional data. Also, both the SF-36 and job-strain variables were based on self-report. Nevertheless, the SF-36 is associated with a range of objectively and subjectively assessed health measures[13,17,20] and thus should be relatively free of bias.

TABLE 4—Logistic Regression Models: Odds Ratios (95% Confidence Intervals) for Emotional Health Dimensions

Independent Variable[a]	Social Function: High (100) vs Low (0–99)	Role Function/ Emotional: High (100) vs Low (0–99)	Mental Health: High (80–100) vs Low (0–79)	Health Distress: High (95–100) vs Low (0–94)

Note. Models control for continuous age; gender (male = 1, female = 0); race (White = 1, non-White = 0); and continuous education.

[a]Continuous variables and ranges: (1) workplace support (2 to 10); social support (5 to 25); (3) number of chronic conditions (0 to 3 or more); (4) job insecurity (3 to 15); (5) physical job demands (1 to 5); (6) life satisfaction (1 to 5); (7) satisfaction/material (4 to 20); (8) satisfaction/social (2 to 10). Dichotomous variables: (9) job strain, entered as a set of three dummy variables with high strain as the comparison group; (10) 1 = married, 0 = not married; (11) 1 = manual work, 0 = professional, sales, clerical, service work; (12) 1 = nonmanual work, 0 = manual, sales, clerical, service work; (13) 1 = full time, 0 = part time.

*$.001 < P \leq .01$; **$P \leq .001$.

We were also hindered by the nonparametric distributions of six of the dependent variables, which necessitated a logistic analysis. Thus, we know that job strain is useful in differentiating the "very healthy" from everyone else in the sample. However, we are not able to make more refined comparisons.

We also add an important caveat. The relationships between life satisfaction (i.e., feeling good or bad about one's circumstances) and some of the subscales must be viewed critically because the independent variable may be conceptually overlapping with some dependent variables.

Despite the fact that job strain reached levels of statistical significance in five models, it was sometimes less significant than other variables. We speculate that results may reflect an indirect pathway linking job strain to health-related quality of life. Job strain may operate directly on health-related quality of life by influencing one's perception of functional ability and well-being. However, job strain may also operate on functional ability and sense of well-being indirectly by contributing to the production of physical or mental disease; that is, health-related quality of life is a response to disease or its precursors. Thus, job strain may operate as both a proximal variable, having a relatively direct and immediate influence on health-related quality of life, and as a distal variable operating through the more proximal or mediating influences of stress-induced disease. The latter statement is consistent with the job-strain hypotheses constructed by Karasek, Theorell, and others.[1]

The lack of a significant interaction between job strain and workplace support or general social support indicates that there were no significant buffering effects. The buffering role of workplace support remains controversial,[26] and recent studies have produced results conflicting with our own.[10] Our workplace-support variables may have been too narrowly defined to be statistically significant.

Establishment of job strain as a risk factor for health-related quality of life awaits further study. Studies of the health effects of chronic, long-term exposure to high-strain jobs, in accordance with recent research on Swedish workers by Johnson and Stewart,[27] suggest that it would be potentially fruitful to measure job strain at multiple points in time. In addition, we were unable to assess cumulative strains on worker health by including data pertaining to marital and parenting roles, financial problems, or other factors. However, analyses of the interplay among work, family, and community would strengthen research on both job strain and health-related quality of life.

Our study argues for continued attention to job roles as health risks. Because jobs are socially structured, the additional

risks associated with high-strain jobs should be considered preventable. □

Alcohol and Drug Disorders among Physically Abusive and Neglectful Parents in a Community-Based Sample

Kelly Kelleher, MD, MPH, Mark Chaffin, PhD, Janice Hollenberg, MS, and Ellen Fischer, PhD

ABSTRACT

Objectives. The purpose of this study was to compare the frequency of substance use disorders and symptoms between adults reporting child physical abuse or neglect and individually matched control subjects in a community sample.

Methods. In a nested case–control study, 169 adults reporting physical abuse of a child and 209 adults reporting neglect of a child from 11 662 individuals successfully interviewed in a probabilistic survey in four communities were individually matched with control subjects drawn from the participants. Case subjects were compared with control subjects on the number of alcohol- or drug-related symptoms and disorder diagnoses as determined by symptoms from the Diagnostic Interview Schedule.

Results. Respondents reporting either physical abuse or neglect of children were much more likely than their matched control subjects to report substance abuse or dependence. These differences persisted after potential confounding variables were controlled for.

Conclusions. Parental substance abuse and dependence, independent of confounding factors, are highly associated with child maltreatment. Inconsistent results in previous studies may have arisen from reliance on referred samples and unstandardized assessment methods. Agencies involved in the care of abused or neglected children and their families should consider incorporating routine substance abuse evaluations with treatment, or referral for treatment, where indicated. (*Am J Public Health.* 1994;84:1586–1590)

Introduction

Over the past three decades, the number of reports suggesting a relationship between child physical abuse or neglect and substance use by parents has grown.[1] Yet a recent national survey of state child protective services agencies revealed that only 14 states routinely collect information on substance abuse.[1] Estimates of the proportion of confirmed child abuse cases associated with some sort of parental substance abuse problem have varied widely, from 5% to 78%.[2] Nevertheless, substance abuse has been termed the "dominant characteristic" of families in the child abuse and neglect caseloads of some states.[3]

Social and environmental factors have been considered primary to the development of both child maltreatment and parental substance abuse. Social class is strongly linked to both reported child maltreatment[4] and a wide range of mental disorders, including drug and alcohol disorders.[5,6] Child physical abuse and neglect have been found to be higher by factors of 3.5 and 8.0, respectively, among lower-income families.[7]

Although social and environmental factors have been considered the primary determinants of child abuse and neglect, some authors[4,8,9] have suggested that parental psychiatric disorder generally, and substance abuse specifically, predisposes to child maltreatment, regardless of social factors. For example, incapacitation or impaired judgment secondary to substance abuse may give rise to child neglect. Similarly, depression has a documented association with child maltreatment.[9] Likewise, antisocial personality traits are associated with substance abuse and child maltreatment.[10] Finally, abusive parents are widely cited as being socially isolated,[11–13] and thus prone to drinking or drug use.

Methodological and sampling problems have left unanswered questions about the strength and nature of the relationship between alcohol and drug disorders and child maltreatment, thereby calling into question the value of increasing efforts targeting alcohol or drug abuse in families referred for child abuse or neglect. Studies comparing *reported* child abusers with their nonabusive counterparts are vulnerable to confounding as a result of the child abuse reporting process, which may disproportionately identify women, people of color, or lower socioeconomic classes. Studies examining rates of child abuse or neglect among clinical populations of substance-abusing parents are subject to similar referral biases.

Moreover, many studies used poorly specified or inconsistent definitions of substance abuse. Often, investigators did not distinguish among substance abuse (a general pattern of maladaptive use with associated social or physical problems), substance dependence (a more specific chronic pattern characterized by a wide

variety of role impairments, tolerance, withdrawal, and loss of control over use),[13-15] and a variety of lesser patterns of substance use. Some authors[12] suggested that reports of drinking found among surveys of abusive parents may simply reflect attempts to present a socially acceptable justification for abusive behavior, rather than reflecting the correspondence between child maltreatment and a bona fide diagnosis of addictive disease.

These concerns led some to conclude that the relationship between substance abuse and child maltreatment is minimal at best.[16] Yet we are aware of no studies that examined the epidemiology of alcohol and drug disorders with physical abuse and neglect that used (1) a probability sample from a community population rather than referred cases, (2) a carefully matched control group, and (3) data-analytic procedures able to adjust for potential confounds.

Methods

The National Institute of Mental Health (NIMH) Epidemiological Catchment Area Study was a community-based survey of 18 000 adults in five communities across the United States. The Epidemiological Catchment Area data provided the best estimates of the prevalence of other psychiatric disorders in the community, and they offer a unique opportunity to compare the frequency of substance abuse and dependence between adults who report having abused or neglected children and those not reporting child maltreatment. Adult respondents reporting abusive or neglectful behaviors (case subjects) were individually matched on sociodemographic factors with adult respondents not reporting those behaviors (control subjects). We hypothesized that abusive adults and neglectful adults would have more alcohol and drug disorders and symptoms related to substance abuse than their control subjects.

Sample and Procedures

The Epidemiological Catchment Area program consisted of sample surveys at five research sites: New Haven, Conn; Baltimore, Md; St. Louis, Mo; Durham, NC; and Los Angeles, Calif. The surveys were coordinated by the NIMH program staff and included a probability sample of 4000 noninstitutionalized individuals from each community.

Once an individual was selected for the sample, repeated attempts as necessary were made to interview the individual. Of the individuals sampled, 65% to 80% were successfully interviewed. Participation rates varied minimally by site, race, sex, and age.[17] The survey consisted of a face-to-face structured interview, using the Diagnostic Interview Schedule,[18] to obtain information on sociodemographics, health service use, psychiatric symptoms, and functioning.

Measures

Cases for this study were defined as all adult respondents who answered "yes" to any one of five questions on abusive or neglectful behaviors included in the Diagnostic Interview Schedule. More specifically, a single question in the Schedule inquires about serious physical abuse of a child resulting in bruises, bed days, or medical care. Participants who responded positively on this item were classified as "abusive." One site (New Haven)[13] did not include this question and was excluded from all analyses.

Four questions inquired about neglectful behaviors, including leaving very young children unattended for extended periods, inadequately feeding or caring for children, or having a health care professional state that children were being neglected. The respondents who reported at least one of these behaviors were classified as "neglectful."

All of the remaining respondents who reported never having had children or never having acted as caretakers for children were then excluded from the potential control group. The abusive adults and the neglectful adults were matched with respondents from the control pool on age (±5 years), race, gender, site, and socioeconomic status quartile. Socioeconomic status scores were determined from a composite of variables including education, household income, and occupational status. Eleven (3.0%) of the abusive or neglectful adults who could not be matched on race were eliminated from analysis. When more than one potential match was generated for a case, one match was randomly selected from among them.

The other primary variables of interest were alcohol and drug disorders. The Diagnostic Interview Schedule used in this study provided computer-generated diagnostic algorithms to derive lifetime *Diagnostic and Statistical Manual of Mental Disorders*, third edition, alcohol abuse, alcohol dependence, drug abuse, and drug dependence diagnoses. Subjects meeting these *Diagnostic and Statistical Manual of Mental Disorders* criteria were coded as positive for the relevant diagnoses. Previous work demonstrated the reliability and validity of the Schedule in detection of alcohol and drug disorders.[19] In addition, the number of alcohol disorder symptoms (out of a possible 17) and drug disorder symptoms (out of a possible 8) was calculated for each respondent. Because of the lack of information about the timing of child abuse or neglect behaviors, lifetime prevalence estimates instead of current prevalence estimates are reported for this study.

Because depression[20] and social isolation[21] have been associated with child abuse and neglect, lifetime history of major depressive disorder (yes/no) and social support, defined as use of friends and/or relatives as confidants (yes/no) or use of a social service agency for problems with emotions, nerves, drugs, alcohol, or other mental health problems (yes/no), were coded from the Diagnostic Interview Schedule. Because antisocial personality has been associated with excessive drinking and drug use,[22] the presence of antisocial personality was entered in regression models to examine the extent to which substance abuse disorders independently contribute to child physical abuse and neglect.

The number of individuals in a household was included in the regression model to control for the effect of the cluster sampling scheme, which oversampled individuals living alone, and to control for the demonstrated association between family size and child physical abuse and neglect.[7] Finally, to screen for a general "yes" response set, cases were assessed for the presence or absence of another disorder diagnosed by the Diagnostic Interview Schedule. Panic disorder was chosen because there was no theoretical or empirical evidence to suggest a relationship between panic disorder and child maltreatment.

Analytic Plan

Statistical methods for matched-pairs data were employed. McNemar's test was selected for comparing case subjects with control subjects on categorical variables. The Wilcoxon signed rank test was used for ordinal measures, such as the number of lifetime symptoms related to alcohol or drug disorders.

TABLE 1—Demographic Profile of Case Subjects (Those Admitting Physical Abuse or Neglect of Children) and Control Subjects

	Abuse		Neglect	
	Case Subjects, % (No.)	Control Subjects, % (No.)	Case Subjects, % (No.)	Control Subjects, % (No.)
Age, y[a]				
18–24	8.9 (15)	8.3 (14)	17.7 (37)	13.9 (29)
25–44	69.8 (101)	59.2 (100)	51.2 (107)	56.0 (117)

[a]Matched-pair odds ratio.
*$P \leq .05$; **$P \leq .01$; ***$P \leq .001$.

Conditional logistic regression for paired data was used to predict group membership (abuse cases vs control group; neglect cases vs control group) on the basis of the presence or absence of a drug or alcohol disorder, after controlling for depression, number in household, antisocial personality disorder, and social support.

Results

A total of 11 662 of the individuals who were successfully interviewed across the four sites did not deny being parents or acting as a caretaker for children. A total of 169 respondents (1.4%) reported abusive behavior, whereas 209 respondents (1.8%) reported neglectful behavior. Sixteen respondents (0.1%) reported both physically abusive and neglectful behavior. The inclusion of respondents reporting both abusive and neglectful behaviors did not significantly change the findings of the study. Results are presented with these individuals categorized as case subjects for both child abuse and neglect.

Table 1 presents the demographic profile of respondents admitting physical abuse or neglect. The mean age of both abusive and neglectful adults at the time of interview was 40 years. The abusive group was predominantly White (61%) with a high school education (51%) and an average socioeconomic status score of 45 (out of a possible range of 0 to 100), whereas the neglectful group consisted primarily of non-Whites (63%) with less than a high school education (61%) and a lower average socioeconomic status score (38%).

In Table 2, the results of the comparisons between case subjects and control subjects for presence of alcohol or drug disorders are presented. The lifetime prevalence of alcohol or drug disorders among subjects admitting physical abuse or neglect of children is markedly higher than that among their matched control subjects, almost without regard to type of diagnosis considered. Control subjects had prevalence rates similar to those reported among the entire sample of household respondents. Both control groups reported on average less than one alcohol or drug symptom, whereas their respective case counterparts reported substantially higher averages.

Results of the logistic regression for paired data (Table 3) give the estimated odds ratio for child physical abuse or neglect for those with a substance abuse disorder after simultaneously controlling for depressive disorder, number in household, antisocial personality disorder, and social support. Substance abuse or dependence continued to be a significant predictor of both child abuse and neglect. In fact, those adults with an alcohol or drug disorder were 2.7 times more likely to have reported abusive behavior toward children and 4.2 times more likely to have

reported neglectful behavior toward children than were their matched control subjects. Adults living in larger households or with a history of depressive disorder were also significantly more likely to have acted abusively toward children than their matched control subjects. A history of antisocial personality disorder remained a significant predictor of child neglect. Interpretation of this finding should be tempered by the consideration that child-maltreatment items are embedded in the antisocial personality disorder diagnosis, thereby increasing the possibility of finding an association between the disorder and child maltreatment. However, regression models omitting the antisocial personality disorder variable produced results similar to those reported here.

Because of concerns about a positive response set among those adults reporting high rates of symptoms, we examined the frequency of panic disorder across cases. Fewer than 5% of neglectful case subjects and 7% of abusive case subjects reported symptoms sufficient to meet criteria for panic disorder, suggesting that the high rates of substance abuse and dependence found in our study were not the result of a general positive response set. The frequency of panic disorder was slightly lower in control subjects.

TABLE 3—Odds Ratios and 95% Confidence Intervals for Child Abuse and Child Neglect and the Proportions of Case and Control Subjects

	Odds Ratio	95% Confidence Interval	% Case Subjects/ % Control Subjects

[a]Mean.

Discussion

This is the first controlled study to use a community-based sample with standardized diagnoses and assessments to explore the prevalence of alcohol or drug disorders among physically abusive and neglectful parents and caretakers. Forty percent of the adults reporting physically abusive behavior and 56% of the adults reporting neglectful behavior met criteria for an alcohol or drug disorder during their lifetime. These rates of substance abuse disorders were markedly higher than those found in a control group matched on age, race, gender, socioeconomic status, and site. The physically abusive and neglectful groups were also found to report more drug or alcohol disorder symptoms than their respective control subjects. The contribution of substance abuse disorders to predicting physical abuse or neglect remained significant after controlling for depression, household size, antisocial personality disorder, and social support.

Although the differences noted in this study are highly significant and correspond with anticipated results, it is important to underscore some limitations. First, the data are retrospective and do not include information on the temporal sequencing of drug or alcohol disorders and abuse or neglect of children. As a result, no causal inferences can be made. However, heavy users of drugs and alcohol often initiate their use in early adolescence,[23,24] before becoming parents, suggesting that substance abuse disorders are likely to be established or in process when parenting tasks are first encountered. In this study more than 25% of case parents or caretakers with substance abuse disorders began using alcohol or drugs before age 15. Additionally, it is not possible to ascertain the contribution of drugs or alcohol to *individual* acts of maltreatment. However, it is likely that the impact of drug or alcohol use at a level sufficient to warrant a formal diagnosis probably extends well beyond the immediate effects of use.

Second, the prevalence of abuse and neglect found in these data is similar to the prevalence of abuse found in a Canadian study using the Diagnostic Interview Schedule[9] and higher than the prevalence garnered from child welfare agencies. However, it is below the generally accepted prevalence of abuse and neglect in the population and is approximately equal to the estimated annual incidence rates found in other studies.[12] A number of factors may account for this result. First, only one respondent per household was interviewed, thereby underestimating the number of children abused or neglected because most children are "exposed" to more than one adult. Second, child-maltreatment behaviors are probably minimized or hidden due to the social stigma attached to the problem and are likely to be underestimated by self-report data. However, if social desirability bias or concern about self-incrimination caused some maltreating respondents to be classified as control subjects, the effect on the study should be to reduce observed effect sizes by falsely classifying some abusive or neglectful parents as control subjects. On the other hand, respondents falsely denying both child maltreatment and substance abuse disorders could increase our observed effect size.

Finally, the Diagnostic Interview Schedule does not sample the entire range of child physical-abuse and neglect behaviors. The content of the physical-abuse question suggests that parents were only asked about relatively serious occurrences. Thus, these findings could be consistent with Steele's contention that alcohol abuse is a greater factor among the more severe cases of physical maltreatment.[8]

Although this study cannot conclude a causative relationship, the use of a community sample and matched control subjects suggests that the relationship between parental substance abuse and child maltreatment is robust and cannot easily be dismissed on the basis of referral patterns, social class, or community of residence. It is also unlikely that a generic "yes" response set to psychiatric symptoms by some respondents resulted in the association, as neither case subjects nor control subjects were likely to receive a diagnosis of panic disorder, a condition

with no theoretical or empirical link to child maltreatment. Finally, the results support the hypothesis that depression, antisocial personality disorder, or lack of social support mediates some of the relationship between substance abuse and the types of maltreatment studied.

Our results suggest that parental psychopathology, independent of social ecology, is an important determinant of child maltreatment in many cases. Recognizing substance abuse in maltreating parents may alter treatment and outcomes for families in child welfare services. For example, it is widely accepted that maltreating parents with substance abuse disorders must receive treatment for their disorder before any interventions for maltreatment with the family are likely to be effective.[25]

Currently, most maltreating families do not receive a specific substance abuse evaluation,[14,26] and among known substance abusers in one study, fewer than half of the maltreating parents were referred for alcohol or drug treatment.[14] Data from one state reveal that substance abuse was identified as a problem in only 8% of substantiated child abuse or neglect cases, and treatment was provided for only 4%. Child welfare systems will need to carefully examine their child maltreatment case-finding mechanisms and their substance abuse evaluation and treatment programs. □

Consequences of the North American Free Trade Agreement for Health Services: A Perspective from Mexico

ABSTRACT

Objectives. The purposes of the study were to assess the potential impact of the North American Free Trade Agreement (NAFTA) on medical care in Mexico and to identify internal measures Mexico could take to increase the benefits and minimize the risks of free trade.

Methods. The dual nature of the health sector is examined; the Mexican, Canadian, and US health care systems are compared; and modes and consequences of international exchange of health services are analyzed.

Results. Four issues require immediate attention: accreditation of health care facilities, licensing and certification of professionals, technology assessment, and financial equity.

Conclusions. NAFTA offers opportunities for positive developments in Mexico, provided risks can be anticipated and preventive measures can be taken to avoid negative impacts on the health system. Medical services, like other elements of the Mexican economy, must be modernized to respond to the demands of global competition. The Mexican National Academy of Medicine has recommended to the Mexican government (1) internal strengthening of the Mexican health care system to improve its ability to respond to the new conditions created by NAFTA and (2) a gradual process to facilitate equitable and mutually beneficial interactions among the three countries. Introduction

After a tense and intense debate, the North American Free Trade Agreement (NAFTA) gained formal approval for implementation beginning January 1, 1994. In the midst of the discussion about the agreement's immediate economic effects, its long-term impact on social sectors such as health received far less attention. In Mexico the NAFTA negotiation process, initiated 2 years ago, did trigger a policy debate on the future of the health system. In this article we discuss why NAFTA could have far-reaching effects on personal health services in Mexico, identify the nature of those effects, discuss their potential risks and benefits to society, and summarize the recommendations offered by the Mexican National Academy of Medicine in 1992 to the Ministry of Trade and Industrial Development, the agency leading the NAFTA negotiations for Mexico.[1]

Economic integration and trade liberalization are bound to have profound effects on every aspect of social life in Mexico. In health, NAFTA will influence five major areas: environmental and occupational health; regulation of food, drugs, water, and sanitation; capital investments in facilities and development and sales of medical equipment, devices, pharmaceutical products, and other such "inputs" for health care; training and utilization of personnel; and regulation, financing, and delivery of health services.

The first three of these areas are clearly linked not only to the health of the population but also to overall economic growth. Therefore, they were an integral part of discussions about NAFTA since the early stages. In contrast, the last two areas were subsumed under a broader negotiation group dealing with the entire service sector of the economy.

To help fill the resulting analytic gap, we focus on the implications of NAFTA for the regulation, financing, and delivery of personal health services. The central point of this paper is that, just like the rest of the economy, health services in Mexico must be modernized to respond to the demands of global competition. This process of modernization makes issues such as accreditation of health care units, licensing and certification of professionals, technology assessment, and financial equity important topics for examination and discussion. Attention to these issues can strengthen the capacity of the state to define and enforce standards to promote quality, protect consumers, and help guarantee basic equal opportunities for all Mexicans.

In the first part of the paper we discuss the characteristics of health and health care that must guide the analysis of the consequences of NAFTA. In the second part we compare the Mexican, Canadian, and American health systems. We then move to an examination of the effects of NAFTA on the main modes of

international exchange of health services and end with a series of recommendations. Although our analysis centers on Mexico, we hope it will stimulate more dialogue with those familiar with the Canadian and American points of view.

The Dual Nature of Health Services

Understanding the special character of health services is a prerequisite to any analysis of their relationship to trade liberalization. Unlike other products, health services have a dual nature. On the one hand they represent a fundamental component of social development and well-being; on the other, a growing sector of the economy.

In modern times, the quest for health has been strengthened by unprecedented advances in science and technology. Although the health status of a population is fundamentally determined by its living conditions, personal health services can substantially change the incidence and severity of disease.

The fact that in this century health services have become effective has given them a positive value and made them the object of increasing demand by society. Thus, access to such services has become an indicator of the quality of life in a community. Health is not only one of the ultimate aims of economic growth; it is also one of its conditions, because it is a determinant of productivity. In addition, the provision of health services has been used as a means for redistributing wealth and, together with education, as a fundamental element in the promotion of equal opportunities. Because of their connection with the essential processes of life—birth and death, enjoyment and pain—health services are at the center of solidarity. Access proportional to need—not to privilege or ability to pay—has become a fundamental component of equity and social justice.

At the same time, the financing and delivery of services has become a dynamic sector in all modern economies.[2] It is an important source of employment, a generator of demand for all kinds of inputs, and a driving force for technological innovation. As such, it has fueled the emergence of a vast medical-industrial complex. However, the market for medical services is far from perfect. Among its most important imperfections are externalities, uncertainty, consumer ignorance, induced demand, and monopolistic conditions.[3] Together with the ethical aspects of medical care and the role of health in social well-being, these market imperfections mean that a collective mediator between producers and consumers—which in all modern societies is the state—is required in order to obtain an optimal distribution of resources, protect the interests of the community, and ensure maximum social benefit from health services.

The complex subject of state intervention in the field of health goes beyond the scope of this paper. Suffice it to say that the state can carry out three fundamental activities related to personal health services: regulation, financing, and direct delivery.[4] Regulation has always been a public responsibility, but there has been substantial variation in government control over financing and delivery across different countries and at different moments in history. For this reason, analysis of the effects of NAFTA requires that we first examine the structure and function of the health systems of Canada, Mexico, and the United States, with emphasis on these three activities.

Comparative Analysis

Good descriptions of the health systems of Canada, Mexico, and the United States already exist in the literature.[5–7] Because many North American readers are likely to be less familiar with the Mexican situation than with health conditions and services in Canada or in the United States, and because Mexico is dissimilar to Canada and the United States in ways that become even more important under trade liberalization, we provide a discussion of the salient features of the Mexican health system. This discussion supplements the information presented in Table 1, which presents various indicators of health conditions, expenditures, and resources in the three NAFTA countries, and Table 2, which shows the main causes of death in each country.

Because the Mexican Constitution has explicitly recognized a right to health protection, it assigns a key role to the state in conducting national health policy. The National Health System is made up of three components. The first includes those governmental organizations providing services for the uninsured population, principally the rural and urban poor. The main institutions involved are the Ministry of Health, the National Institutes of Health, the IMSS–Solidarity Program, the Health Services of the Federal District,

and an agency in charge of family welfare. The second component, social security, comprises an institute covering workers in the formal private sector of the economy (Instituto Mexicano del Seguro Social [IMSS]) plus separate organizations for federal civil servants, some local government employees, the armed forces, and the employees of the national oil company. In contrast to the European experience, social security in Mexico has developed its own network of hospitals and salaried personnel, thereby combining the financing and delivery of services in a single agency. The third component, the private sector, is made up of a collection of health care providers working in hospitals, ambulatory clinics, offices, and indigenous (folk) medicine on a for-profit basis.

Almost 55% of the population subscribe to a social security institution, 35% receive care from agencies for the uninsured, 4% always use private services, and 6% have no easy access to permanent facilities (although they may benefit from special campaigns, such as vaccination campaigns, which have achieved virtually universal coverage). Revenue for public institutions is drawn from three sources: (1) the federal budget; (2) employee and federal contributions that finance social security benefits for civil servants; and (3) employees and employers in the private sector and a federal subsidy for the social security institute covering private sector workers. There is little voluntary medical insurance; instead, a large proportion of payments to private providers are made directly by the patients.

The government has major responsibility for financing, for providing services, and for regulating health-related activities. However, this last function has often been limited to issuing rules, while enforcement has remained weak. Responsibility for licensing of health professionals falls on institutions of higher education rather than on the National Health Service. Current procedures require that degrees be endorsed by the Ministry of Public Education. The National Academy of Medicine, a private nonprofit organization, coordinates the certification of specialists. Absence of certification of a physician in a specialty imposes no legal restriction on his or her practicing in that or any other specialized field of medicine.

When the Mexican system is compared with those of its North American neighbors, profound imbalances among the three countries become apparent (Table 3). Each system has its own strengths and weaknesses. Mexico has the benefit of a constitutional right to health protection and a recognition of health as one of the main components of social policy.[8] Health institutions currently extend care to almost the entire population. The Mexican system's principal weakness is its segmented nature, which results in large gaps in the quality of care provided to different population groups. The strength of the Canadian system is its universal coverage with a high degree of equity and decentralized control that has preserved consumer choice of primary provider. Recently, however, this system has been facing cost control problems. The American system is outstanding for its scientific and technological development but is confronting a severe crisis

whose central elements are incomplete coverage of services; fragmentation of the system, with striking inequalities; an escalating rise in costs; excessive use of technology; and an expensive combination of legal complaints and defensive medical practice.

Beyond the characteristics of each system, a comparative analysis reveals profound imbalances. These include

- Imbalances in health conditions, including major differences in mortality, morbidity, and fertility as well as in patterns of epidemiological transition.
- Imbalances in resources devoted to health care. Mexico spends, in absolute terms, 1/10 the amount spent by Canada and 1/30 the amount spent by the United States.
- Imbalances in the regulation of health services. Mexico lags behind Canada and the United States considerably in accreditation of health care facilities, certification of practitioners, and technology evaluation.
- Imbalances in the dominant forms of financing. In Mexico, these are mostly public and centralized; in Canada, they are public and decentralized; in the United States, the complex mixture includes decentralized private insurance, public centralized insurance (Medicare), and insurance sponsored by the state and federal governments (Medicaid).
- Imbalances in the forms of private sector participation. In Mexico participation is fragmented and is financed mainly by direct payment from the patient, whereas in the United States private medical insurance is the dominant form of financing.
- Imbalances in the power of the patient. Whereas in the United States patients may file excessive lawsuits, in Mexico patients with low purchasing power have little recourse if they are dissatisfied with the quality of services rendered.
- Finally, one feature that distinguishes the Canadian and American systems from the Mexican system is the separation between financing and delivery of services (although health maintenance organizations tend to bring both functions together). In Canada the combination of equitable financing with predetermined expenditure limits appears to account for better health system performance than in the United States.

One of the few features common to the three systems is the predominance of curative medicine.

A primary and paradoxical conclusion based on this analysis is that Mexico is the NAFTA country with the highest degree of direct government involvement in the financing and delivery of health services but the weakest capacity to regulate the private medical care market.

Given the marked asymmetries among the health systems of the three countries, what is the likely impact of trade liberalization on Mexico, the least developed link in this commercial chain?

The European Experience

In attempting to answer this question, it is useful to consider the European Economic Community (EEC) as a precedent. The fundamental tenets of NAFTA differ from those of the EEC. NAFTA is a limited treaty involving only the movement of goods, services, and capital. It does not imply the level of integration of the EEC. Additionally, the differences between Mexico and its two neighbors are huge in comparison with the differences between poor and rich countries of the EEC. As Schlefer states:

> NAFTA is an experiment in opening the economies of industrialized nations to a major Third World country. Japan has no such agreement with its East Asian trading partners, and although the European Community admitted Spain, Portugal, and Greece into its memberships, they are not comparable to Mexico. Spain has a per capita income close to half that of the U.S., while Mexico's is a tenth as high. Portugal and Greece are poorer than Spain but still have per capita incomes twice Mexico's, and they contain only six percent of the total population of the EC; Mexico contains almost a quarter of North America's population. The EC is bringing poorer member countries up to Community standards with billions of dollars of development assistance and the enforcement of common environmental and workplace regulations. . . . In contrast, NAFTA proposes that the U.S. and Canada take Mexico as is, while Mexico pays back a debt close to $75 billion—a kind of Marshall Plan in reverse.[9(p114)]

In contrast to NAFTA, the EEC has been firmly committed to an integrated social policy intent on defining and managing environmental, health, labor, and social relations in each of the member countries. The EEC agreement establishes the right to free movement in EEC countries for all EEC workers. This freedom of movement is accompanied by the guarantee of social security eligibility in whichever member state a worker resides.[10] The EEC's social charter, established in 1961, specifies the right to social security and medical coverage, occupational safety, decent remuneration, membership in national and international labor organizations, collective bargaining, and vocational training. It also provides for the social and economic protection of children and pregnant women.[11]

Modes of Interaction

Even before NAFTA was ratified, trade liberalization was producing changes in Mexican society. It is unlikely that the National Health Service will remain immune to such changes. Among other effects, NAFTA will lead to a more intense exchange of personal health services, especially between the United States and Mexico. Below we discuss five major modes of exchange: movement of service users, movement of service providers, establishment of health care units in other countries, exportation of services, and international joint projects.

Movement of Service Users

This phenomenon is already prevalent along the border between Mexico and the United States. Trade liberalization caused by the creation of free zones and the expansion of the *maquiladora* industry has generated a large demand for health services along this border. The patterns identified are likely to intensify, and they portend national effects under NAFTA.

Two problems arise as a result of this growing interaction. First, inadequate formal channels of communication, referral, and follow-up between providers on different sides of the border are likely to have a negative impact on the continuity, quality, and costs of care. Second, the absence of financing mechanisms to pay for health services regularly received across the border (nonportability of insurance) has repercussions on accessibility, equity, and efficiency.

Movement of Health Service Providers

Under NAFTA, health service providers may eventually cross borders to deliver services in another country. A potential advantage is improvement in the cultural match between consumers and providers for citizens who have migrated (i.e., Mexican health professionals could serve Mexican Americans in the Southwestern United States and US health professionals could serve American retirees in Mexico). Such exchanges could

improve the transfer of knowledge and clinical procedures. For health professionals to practice in these neighboring countries, licensing and certification criteria in the NAFTA countries must be made consistent and interchangeable.

Establishment of Health Care Units in Other Countries

There are few examples of foreign medical care units established in the North American region. Presently there is no legal restriction on investment in this area in Mexico, yet it took a structural adjustment program and NAFTA to create a more entrepreneurial atmosphere that is likely to lead to the development of a foreign health care industry in Mexico. Many local providers may face considerable disadvantages compared with foreign corporations, owing to preferences of the upper and middle classes in Mexico and to such problems in the Mexican private sector as outdated technology, uneven quality of medical care, and limited financial capacity for growth. Another factor that might facilitate the establishment of American corporations in Mexico is the lax character of Mexican legislation regarding the installation of health care units, whether national or foreign.

Nevertheless, foreign medical care units should not represent a threat to the National Health Service. It is doubtful that immediate dramatic changes will result from NAFTA. Therefore, Mexican organizations will have time to adapt. In addition, trade liberalization offers potential benefits. Foreign health care units can satisfy unmet needs, create jobs, decrease capital flight by reducing the number of Mexican consumers seeking health care abroad, promote competition beneficial to consumers, and introduce efficient models of service delivery and managerial technology (cost accounting, prepayment systems, etc.).

To achieve these potential benefits, Mexico must have regulation sufficient to avoid intrusion of the sorts of inequities and inefficiencies characteristic of the American system. In particular, it will be imperative to deter patient discrimination and unnecessary procedures. For the establishment of foreign units to have a positive impact on the existing system, Mexico will require effective means of ensuring equity, quality, and cost containment. Experience shows that such measures are best implemented before the market opens. Otherwise, vested interests are likely to increase the political and economic costs of introducing reforms.

At the same time, trade liberalization creates opportunities for the establishment of Mexican health care units in the United States. The high costs of medical care and the insufficient coverage of many Hispanic populations offer Mexican providers the opportunity to address the needs of a significant market.

Export of Services

The exchange of diagnostic or therapeutic information among institutions providing health care in different countries amounts to export of services, often by telecommunication. Although it holds much potential for the future, this mode of interaction has the least likelihood of implementation in the short term, because it will depend on substantial communication infrastructure and standardization of referral patterns.

Cooperation in International Joint Projects

Another interesting opportunity offered by NAFTA involves the development of international consortia. Joint projects could introduce innovations in the delivery and financing of health services. Equally attractive are proposals for linking programs of scientific research and higher education for mutual benefit. Some cooperative projects already exist in the region, and NAFTA will provide the impetus for more.

Consequences of Trade Liberalization

The NAFTA text contains minimal references to personal health services. Most of the sections devoted to health relate to sanitary regulation and to occupational and environmental health. However, Annex 1210 includes a provision that is relevant to medical services. This provision indicates that "relevant bodies" will negotiate "mutually acceptable professional standards and criteria for licensure and certification of professional service providers and [will] provide recommendations on mutual recognition."[12]

Beyond this specific provision, the five modes of interaction are likely to create opportunities and risks for Mexico that must be borne in mind in order to optimize potential benefits and minimize risks. Table 4 summarizes some possible consequences of NAFTA; it contrasts the prospects in Mexico with those for the United States and Canada, although obviously there are great differences between the latter two.

As suggested by Table 4, NAFTA will create the possibility of expanding the market for the medical-industrial complex in Mexico. It is likely to promote national and foreign investment, which in turn will create jobs and improve the technological content, competitiveness, accessibility, quality, and productivity of health services in Mexico.

The major risks relate to a greater dominance of curative medicine, a lack of consumer protection from unqualified providers, possible brain drain, an increase in the practice of defensive medicine, cost inflation, deeper inequalities, and underutilization of the medical infrastructure already in Mexico.

Whereas taking advantage of the opportunities will require various structural changes and trade strategies, minimizing the risks does not imply large direct costs but does require political will.

Recommendations

A variety of recommendations consistent with the preceding analysis were offered by the Mexican National Academy of Medicine to the Mexican government in December 1992. A summary of the advice follows. One set of recommendations is directed to internal strengthening of the National Health Service with the objective of increasing its ability to respond to the new conditions. A second set is intended to deal with the exchange of services among the three countries.

Internal Strengthening of the Health System

Despite the asymmetry of health care resources among the three countries, Mexico has been able to develop an ample infrastructure. Hence, the first priority is protection of progress already achieved in institutional development, training of the health services work force, and extension of coverage. At the same time, it is necessary to identify the structural aspects of the National Health Service that may complicate the pursuit of opportunities offered by NAFTA and the reduction of NAFTA-related risks.

Like the rest of the economy, health services in Mexico must be modernized to respond to the demands of global competition. Given market imperfections, strengthening the capacity of the state to define and enforce standards that will promote quality and protect consumers

TABLE 4—Opportunities and Risks of the North American Free Trade Agreement for Mexico in the Health Care Areas

Mode of Interaction	Opportunities		Risks	
	Direct	Indirect	Direct	Indirect
Movement of users				
Americans and Canadians to Mexico	Market expansion Economies of scale Growth in the medical-industrial complex Currency earnings Establishment of referral systems Greater freedom of choice for users	Incentives for improvement in quality Incentives for investment Growth of the private sector and insurance Reduction of unemployment and underemployment in the medical sector Creation of jobs in complementary economic sectors	Discrimination against Mexican patients Increase in care costs More lawsuits against Mexican providers Spreading of infectious diseases	Increase in profit-oriented medicine Problems in disease control and surveillance
Mexicans to the United States and Canada	Access to specialized medical procedures and technology	Satisfaction of needs not met in Mexico	Underutilization of the medical infrastructure in Mexico	Fall in investment Capital flight Reduction in local revenue
Movement of providers				
Americans and Canadians to Mexico	Greater choice for Mexican users Complementarity of medical services Improvement of Mexican procedures for professional licensing to bring them in line with international standards Increase in competition Better quality of care	Strengthening of Mexican regulatory bodies Wider market for Mexican medical schools and faculties to train Americans and Canadians Better quality of health professional education	Increase in unemployment and underemployment of Mexican physicians Strengthening of predominance of curative medicine Increase in costs Selective movement of the least competent providers	With inadequate agencies, lack of protection for Mexican consumers With inflexible rules, defensive medicine Resurgence of inequality Capital flight due to currency remittances
Mexicans to the United States and Canada	Satisfaction of Hispanic demand for care	Improved continuing education for Mexican providers	Lack of interest in Mexican market Brain drain	Increase in costs
Establishment of units				
American and Canadian units in Mexico	Increase in foreign investment Satisfaction of demand for health services by population segments with ability to pay Technology and knowledge transfer	Creation of jobs Greater competition Development of private medical insurance Renewal and expansion of medical-industrial complex Greater coverage	Fall in investment in local capital Deeper inequities Unnecessary medical treatment Transfer of inefficiencies Transfer of environmental and occupational risks	Financial crisis for Mexican private institutions due to fall in demand Fall in public responsibility for satisfaction of social needs
Mexican units in the United States and Canada	Access to Hispanic market	Solidarity with Hispanic groups and legal and illegal Mexican seasonal workers	...	...
Services				
Importation	Adoption and improvement of international norms and standards	Improvement of communications structure	Disincentives to scientific and technological research and development Reduction of local investment Capital flight	Worsening of foreign dependence Increase in costs
Exportation	Currency earnings Vertical integration of medical-industrial complex	Incentives to investment Creation of jobs Scientific and technological development	Lack of interest in Mexican market	Increase in costs
Joint projects	Establishment of formal means of interaction Exchange of information Better educational opportunities Complementarity of services Increased mutual understanding	Increase in financial resources for research and education Optimization of resources Strengthening of research and education programs Enhanced common security	...	...

merits the highest priority. To this end, the establishment of new health care facilities in Mexico should conform to rules that are explicit, not ambiguous as they have been to date. We do not suggest that this process should be centralized. On the contrary, at least part of the accreditation authority should be decentralized to Mexico's constituent states, while maintaining minimum quality standards for the entire nation. In addition, the formulation of new standards should involve all interested parties. This broad social participation should concentrate on the design of standards while recognizing that the government is responsible for ensuring compliance.

Another area in need of attention is licensure and certification of professionals. Mexico already has a structure for certifying specialists that is similar to those in the United States and Canada. The most important differences between Mexico and the other two countries lie in the licensing of general practitioners and other professionals with a first degree. As is the case in England, medical education sufficient to begin practice in Mexico occurs at the undergraduate level, not as graduate education. Therefore, it is necessary to conduct studies about the best way in which licensing could actually allow verification of the level of competence.

In addition to personnel, technology plays a fundamental role in the quality of care. An enduring mechanism must be established to evaluate rapidly appearing new technologies. The aim is to generate information on the efficacy, safety, and cost-effectiveness of technology to serve as an objective basis for decision making.

Finally, equity of the system must be addressed. Regardless of the configuration of financing and delivery, the state must ensure that no one is excluded from the benefits of health care and that access is proportional to health needs and not to purchasing power.

The legal framework and procedures for the protection of users of health services in Mexico also require modernization. Consumer protection must be strengthened without absorbing resources vital to the continued development of the health services system. To accomplish this balance will require the establishment of a participatory scheme whereby most cases can be resolved at the level of professional disciplinary bodies.

In general, regulatory efforts must seek a balance. A framework of rules that is too lax imposes costs on patients and society, but excesses in regulation also have undesirable side effects.

Proposals for the International Exchange of Services

Undoubtedly, opening the market will produce a profound transformation in the composition of the Mexican National Health System. Therefore, the main recommendation for the NAFTA negotiation process was for Mexico to adopt a position of gradual change. Indeed, time is needed to implement the internal measures suggested above, which are indispensable for the protection of Mexican consumers. Nevertheless, it is possible to formulate short- and middle-term proposals.

Measures worthy of pursuit during the early phase of NAFTA implementation include the following:

1. Reciprocal recognition of private health insurance among the three countries.

2. Payment by public and private American and Canadian insurance agencies for services rendered in Mexico by providers that follow international certification procedures. In particular, Medicare could cover health care expenses of the retired American community in Mexico, which amounts to 12% of social security recipients living abroad.[13]

3. Establishment in Mexico of low-technology facilities—hospitals for the chronically ill, convalescence hospitals, nursing homes—to care for American and Canadian patients.

4. Establishment in the United States and Canada of Mexican medical care facilities for the Hispanic populations living in these countries, as well as for seasonal workers from Mexico and other Latin American countries.

5. Adoption of compatible information systems to speed patient referral, especially in the US–Mexico border area.

Middle-term proposals include a study of the feasibility of Mexican agencies' financing health services provided in the United States and Canada when the patient's needs so require and the establishment of a tripartite group to analyze ways of strengthening linking mechanisms in health care, with the ultimate objective of obtaining the greatest possible benefit for the populations of the three countries.

In conclusion, Mexico faces a process of change offering enormous development potential for health services in terms of improvement, diversification, and expansion. To take full advantage of such opportunities, Mexico must anticipate and address the risks entailed in the process. This will require both analytical capacity and the will to reach mutually beneficial solutions on the part of all interested parties. □

Acknowledgments

This paper is based, with modifications, on a summary of a document that was prepared by the authors as members of the technical secretariat for the Working Group on NAFTA and Medicine established by the National Academy of Medicine of Mexico. We thank the members of this group and particularly Adolfo Martínez-Palomo, who inspired and facilitated our work, first as vice-president and later as president of the Academy. We also acknowledge the participation of the other members of the technical secretariat, Luis Felipe Abreu and Celia Pérez. Stage of Cancer at Diagnosis for Medicare HMO and Fee-for-Service Enrollees

Gerald F. Riley, MSPH, Arnold L. Potosky, MHS, James D. Lubitz, MPH, and Martin L. Brown, PhD

ABSTRACT

Objectives. Health maintenance organizations (HMOs) with Medicare contracts often provide cancer screening and preventive services not covered under fee-for-service. This study compared cancer patients in HMOs and fee-for-service on stage at diagnosis.

Methods. The study examined stage at diagnosis for aged Medicare enrollees in HMOs and fee-for-service, using information from the Surveillance, Epidemiology, and End Results program, linked with Medicare enrollment files. Twelve cancer sites were investigated, and demographics, area of residence, year of diagnosis (1985 to 1989), and education at the census tract level were controlled.

Results. HMO enrollees were diagnosed at earlier stages for cancers of the female breast, cervix, colon, and melanomas and at later stages for stomach cancer. There were no differences for cancers of the prostate, rectum, buccal cavity and pharynx, bladder, uterus, kidney, and ovary. HMO effects were strongest in areas with large, mature HMOs.

Conclusions. Compared with fee-for-service enrollees, HMO enrollees were diagnosed at earlier stages for cancer sites for which effective screening services are available. The earlier detection of certain cancers among HMO enrollees may result from coverage of screening services and, perhaps, promotion by HMOs of such services. (*Am J Public Health.* 1994;84:1598–1604)

Introduction

Because of their cost-containment potential, health maintenance organizations (HMOs) and other managed care delivery systems are cornerstones of many health reform proposals. Consequently, there is considerable interest in how access to and quality of care in HMOs compares with that in fee-for-service. Access and quality are prominent issues in the Clinton Administration's Health Security Act, which calls for evaluation of care provided by individual health plans and for feedback to consumers. Most studies to date have found few differences between HMOs and fee-for-service on access or quality.[1]

Some studies have examined stage of cancer at diagnosis to compare care in HMO and fee-for-service settings because it is strongly associated with survival. These studies have generally found no difference between HMO and fee-for-service in stage at cancer diagnosis.[1–5] With the exception of Brown et al.,[1] these studies have been limited to single HMOs, and most have been limited to one cancer site.

Our study examined differences in stage of cancer at diagnosis between aged Medicare beneficiaries enrolled in HMOs and those treated in fee-for-service. Staff model, group model, and Independent Practice Association HMOs were included. We used Medicare data linked to tumor registry data from the National Cancer Institute's (NCI) Surveillance, Epidemiology, and End Results (SEER) program. Twelve cancer sites were studied: prostate; female breast; colon; bladder; rectum and rectosigmoid junction; corpus uteri and uterus, not otherwise specified; buccal cavity and pharynx; kidney and renal pelvis; melanoma of the skin; stomach; ovary; and cervix uteri. This study extends the work of earlier investigations by including cases from many HMOs, expanding the number of cancer sites studied, and including larger numbers of cases.

We selected these 12 cancer sites because of their varying degrees of potential for screening. Many HMOs with Medicare contracts cover services outside the regular Medicare benefit package, including preventive services, to induce beneficiaries to enroll. Preventive services, which often include cancer screenings and physical examinations, may lead to earlier stages at diagnosis for HMO enrollees.

Methods

Data

At the time of our study, the SEER program received uniformly reported data from nine tumor registries covering about 10% of the US population.[6] We included in our study the following geographic areas with significant Medicare HMO enrollments: Connecticut, Hawaii, Iowa, New Mexico, Detroit, San Francisco/Oakland, and Seattle. As population-based registries, SEER participants col-

Editor's Note. See related editorial by Robertson (p 1566) in this issue.

lect information on each incident cancer case in their reporting areas. Reported information includes month and year of diagnosis, site of cancer, stage at diagnosis, date of death, and county and census tract of residence.

Although SEER data do not constitute a probability sample of the nation, they are the primary source of national information on cancer incidence and survival.[6,7] SEER areas are concentrated in western states, and they involve a lower proportion of Blacks and a higher proportion of persons of "other" races than the US average.

SEER files were matched to Medicare enrollment files on an individual basis with a 94% match rate, as described elsewhere.[8] Medicare enrollment files contain entitlement dates to Part A and Part B, zip code of residence, and months in which the beneficiary was enrolled under a Medicare HMO risk or cost contract. Enrollees in both risk and cost HMOs were included in the study; findings for risk and cost contract enrollees were similar, and the results were pooled for this article. As of December 1989, 76% of Medicare HMO enrollees in SEER areas were in staff or group model HMOs, and 24% were Independent Practice Association HMOs.

Sample Selection

We selected first primary cases diagnosed between 1985 and 1989 in individuals who were 65 years of age or older and who were entitled to Part A and Part B at the time of diagnosis. For ovarian cancer, only cases diagnosed in 1985 through 1987 were selected because staging information was not available for later years at the time of our study. Lung cancer was excluded from the study because of the high number of unstaged cases.

We selected all cases diagnosed while the person was enrolled in an HMO. For each HMO case, two fee-for-service cases were randomly selected with the same cancer site, health service area of residence, and year of diagnosis (1985 through 1987 or 1988/89). A health service area is a geographic area, composed of one or more counties, that is relatively self-contained with respect to the provision of routine hospital care to Medicare beneficiaries.[9] Sample selection was based on health service area to control for geographic differences in provider practice patterns. In 1% of cases, there were insufficient fee-for-service cases in either a given health service area or year of diagnosis. In the former situation, fee-for-service cases were randomly selected from the appropriate registry rather than from the health service area; in the latter situation, fee-for-service cases were selected from other years of diagnosis. For melanomas, two fee-for-service cases were not available for each HMO case in San Francisco/Oakland, resulting in 76 (15%) too few fee-for-service cases from that registry.

TABLE 1—Number of Persons with Cancer and Percentage Distribution across Stage at Diagnosis, by Cancer Site and HMO Status: Aged Medicare Beneficiaries in SEER, 1985 to 1989

Cancer Site	All Persons	Distribution of Staged Cases, %				Unstaged, %

Note. Unstaged cases are excluded. HMO = health maintenance organization; SEER = Surveillance, Epidemiology, and End Results program; FFS = fee-for-service.

Staging

The NCI codes stage at diagnosis using extent of disease information reported by the registries. The registries abstract information from a variety of sources, including inpatient hospital records, outpatient records, and pathology reports. The staging system recognizes four stages: in situ indicates a noninvasive malignancy; local stage indicates an invasive cancer confined to the site/organ of origin; regional stage indicates spread by direct extension to adjacent organs or to regional lymph nodes; and distant stage indicates spread to distant organs or lymph nodes.

Between 3% and 15% of cases were unstaged, depending on cancer site, because there was inadequate information available on extent of disease. Unstaged cases involve relatively high death rates, suggesting that they consist largely of regional and distant cases.[6]

Analysis

We first excluded cases diagnosed through death certificate review or autopsy (1.2% of all HMO cases and 2.1% of fee-for-service cases) and all unstaged cases. We then estimated three separate logistic regression equations for each cancer site using the following dependent variables: Y1 (1 if stage is distant, 0 for earlier stages), Y2 (1 if stage is regional, 0 if stage is in situ or local), and Y3 (1 if stage is local, 0 if stage is in situ).

Distant stage cases were excluded from the second model, and both distant and regional stage cases were excluded from the third. This method has been described by Fienberg[10] and is appropriate in situations in which the levels of the dependent variable are ordered. If there were fewer than 60 distant stage cases for a given site, those cases were pooled with the regional cases. Unconditional logistic regression was used because most site, health service area, and year strata were large, making the use of conditional logistic regression unnecessary.[11]

Odds ratios (ORs) and 95% confidence intervals were estimated according to standard methods from logistic regression modeling.[12] Goodness of fit of the regression models was assessed by comparing observed and expected numbers of cases with late and early stage disease within deciles of estimated probabilities.[13]

The equations incorporated the following independent variables: age, sex, race, marital status, percentage of adults not completing high school at the census tract level, health service area, year of diagnosis, and HMO enrollment status. Age, race, and marital status were included because previous studies have shown an association between these variables and stage for some cancer sites.[14–18] Race was coded as White, Black, Asian (Chinese/Japanese/Filipino), or other.

Previous studies have shown that lower socioeconomic status (SES) is associated with later stage at diagnosis for breast and cervical cancers.[19–21] Education at the census tract level (expressed as the proportion of adults with less than 12 years of education), based on US census data, was used as a proxy for individual SES status. Education is related conceptually and empirically to both knowledge and use of cancer screening tests.[22] In untracted areas, education at the zip code level was used (14% of cases).

Classification of Cancer Sites

We classified cancer sites on the basis of the efficacy of screening for reducing mortality. Evidence on the efficacy of cancer screening is summarized by the Physician Data Query system, a computerized clinical information service on cancer maintained by NCI.[23] Five levels of evidence are cited, ranging from properly randomized, well-designed and conducted, controlled trials (level 1) to opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees (level 5). On the basis of Physician Data Query levels of evidence at the time of our study, we classified cancer of the female breast as having strong evidence for screening; cancers of the cervix uteri, colon, and rectum and melanomas as having moderate evidence; cancers of the prostate and buccal cavity and pharynx as having weak evidence; and cancers of the bladder, uterus, kidney, stomach, and ovary as having no evidence.

Results

HMO enrollees were diagnosed at significantly earlier stages for four sites without controlling for covariates: female breast, cervix, colon, and melanoma (Table 1). The largest difference between HMO enrollees and nonenrollees (i.e., beneficiaries in fee-for-service) was for women with cervical cancer. Fifty-eight percent of HMO enrollees with cervical cancer were

diagnosed at the in situ stage, in comparison with only 38.8% of nonenrollees. There were also large differences associated with melanomas, with 39% of HMO enrollees diagnosed at the in situ stage and only 23.8% of nonenrollees diagnosed at that stage. Differences in stage between enrollees and nonenrollees were smaller in magnitude for breast and colon cancer but were statistically significant in part because of their larger sample sizes.

The percentage of cases for which stage was known varied among sites (Table 1). For most sites, fewer than 10% of cases were unstaged; for stomach and prostate cancers, however, approximately 15% and 10% respectively, were unstaged. There was a significantly smaller percentage of unstaged cases among HMO enrollees than among nonenrollees for five sites: female breast, cervix, prostate, melanoma, and uterus.

Table 2 summarizes characteristics of HMO enrollees and nonenrollees with female breast, prostate, and colon cancers. There were few differences. The average age of HMO enrollees tended to be about 1 year less than that of nonenrollees. There were no important differences by race, registry, or proportion of adults with less than 12 years of education at the census tract or zip code level. More HMO enrollees tended to be married than nonenrollees, reflecting in part their younger age.

About 45% of sample persons were in the San Francisco/Oakland area, reflecting the high enrollment in Kaiser Permanente. Nearly 20% resided in the Seattle area, most of whom were enrolled in the Group Health Cooperative of Puget Sound. The Hawaii registry had the third highest number of sample persons, resulting in a geographic bias toward HMOs in the western United States.

HMO enrollees with breast cancer were less likely to be diagnosed at distant stages than were nonenrollees (OR = 0.73) (Table 3). HMO enrollees were also less likely to be diagnosed at regional stages than at earlier stages (OR = 0.78). Among women diagnosed at the in situ or local stage, there was no effect of HMO enrollment on stage.

HMO enrollees with cervical cancer were only about one third as likely as nonenrollees to be diagnosed at the regional or distant stage (OR = 0.35). The odds ratio for local vs in situ disease was also below one but was not significant.

Among persons with colon cancer, HMO enrollees were less likely to be diagnosed at regional stages than were nonenrollees (OR = 0.85). HMO enrollees with melanoma were less than half as likely as nonenrollees to be diagnosed at the regional or distant stage (OR = 0.44); among cases diagnosed at the in situ or local stage, HMO enrollees were only about half as likely to be diagnosed at the local stage (OR = 0.52).

For persons with stomach cancer, HMO enrollment was associated with distant stage disease (OR = 1.32). The odds ratio for regional vs in situ or local disease was also above one but was not significant.

Chi-square statistics indicating goodness of fit were nonsignificant at the 5% level for all regression equations except one, indicating acceptable fit of the models to the data. (The full results of the logistic regression analyses are available from the first author.)

Because nearly half of the HMO enrollees were in the San Francisco/Oakland registry (most of whom were Kaiser Permanente enrollees), our findings may not represent a general HMO effect. To test the generalizability of our findings, we developed separate models for the following registries for breast and colon cancers: San Francisco/Oakland, Seattle, Hawaii, and all other registries combined. The HMO effects were strongest in the San Francisco/Oakland and Seattle areas (Table 4). For breast cancer cases in San Francisco/Oakland and Seattle, HMO enrollees were diagnosed at significantly earlier stages. For "other" registries, there was a nonsignificant effect of fewer regional stages for HMO enrollees. For Hawaii, there was no pattern of earlier stage for HMO enrollees.

For colon cancer, HMO enrollees were diagnosed at significantly earlier stages in San Francisco/Oakland, Seattle,

TABLE 3—Odds Ratios for the Association of HMO Enrollment Status with Cancer Stage at Diagnosis: Aged Medicare Beneficiaries in SEER Diagnosed from 1985 to 1989

Site of Cancer	Distant vs Earlier Stages: OR for Distant Stage	95% CI	Regional vs Earlier Stages: OR for Regional Stage	95% CI	Local vs In Situ Stage: OR for Local Stage	95% CI
Strong evidence for screening

and Hawaii but not in the other registries combined.

Discussion

Screening Services and Stage at Diagnosis

HMO enrollees were diagnosed at earlier stages for four sites—female breast, cervix, colon, and melanomas—for which there is strong or moderate evidence for screening. The earlier stages we found may be attributable to HMO coverage of procedures such as screening mammograms, clinical breast examinations, Pap smears, fecal occult blood tests, sigmoidoscopies, and physical examinations. (Medicare did not cover Pap smears until July 1990 and screening mammograms until January 1991.) More than 90% of HMOs with Medicare risk contracts include coverage of preventive services in their benefit packages.[1] Kaiser Permanente and the Group Health Cooperative of Puget Sound, the two largest sources of HMO enrollees in our study, provide preventive services for their Medicare enrollees. Most preventive services are not covered under Medicare fee-for-service, and such services are seldom covered under supplemental "Medigap" policies.[24] Studies of service use have found that HMO enrollees receive more cancer screening services than nonenrollees.[22,25,26] The greater availability of screening services in HMOs may be particularly important for the elderly because elderly women use screening mammographies and Pap smears less frequently than do younger women.[27]

Medicare coverage of Pap smears and screening mammograms under fee-for-service began in 1990 and 1991, respectively. If use of these services is increasing because of Medicare coverage, elderly women may experience earlier stages at diagnosis over time for cancers of the cervix and breast. Future analyses of SEER data can reveal whether this is occurring and whether the distribution of stage at diagnosis in fee-for-service becomes more like that in HMOs over time. Burg and Lane[28] argue that Medicare payment for screening mammography is unlikely to substantially increase use, however, based on physician attitudes toward mammography for older women.

We found that HMO enrollees were diagnosed at significantly earlier stages for melanomas. This type of cancer may be amenable to detection during a routine physical examination or other physician encounter. Although Medicare does not cover routine physical examinations under fee-for-service, 82% of HMOs with risk contracts covered such examinations for their Medicare enrollees as of December 1989. Brown et al.[1] found that HMO enrollees were somewhat more likely than nonenrollees to have a physical examination and were more likely to have at least one physician visit in a year.

Although previous studies have shown that HMO enrollees tend to use more preventive services than nonenrollees, it is not clear whether this is due to insurance coverage of such services or to promotion of their use by HMOs. Luft,[29] in a review of the literature, suggested that differential use of preventive services is due to an "insurance effect" (i.e., financial coverage) and not to an HMO "health maintenance effect." Manning et al.,[30] however, found evidence for both effects. Brown et al.[22] found that HMO membership was associated with both knowledge and use of fecal occult blood tests, suggesting that part of the HMO effect on use of screening services may be due to preventive health education, as well as increased access. Another explanation, however, is that prevention-oriented individuals may have self-selected into HMOs. Such prevention-oriented persons may have sought out screening services even if they had not enrolled.

With the exception of stomach cancer, we did not find differences in stage between HMOs and fee-for-service for sites lacking routine screening procedures. This finding is consistent with a lack of systematic differences between HMO and fee-for-service care in access to services related to cancer diagnosis for those sites lacking routine screening procedures. It is also consistent with a lack of systematic differences between enrollees and nonenrollees in their care-seeking behavior for symptoms indicative of cancer.

Other studies have tended to find no differences in stage at diagnosis between HMOs and fee-for-service. A reason that our findings differ from those of other studies may be that our study was restricted to the elderly population, most of whom did not have insurance coverage of preventive services outside an HMO setting. We also had much larger sample sizes than were available in previous studies.

Although we found earlier stages at diagnosis for HMO enrollees, we did not determine whether survival was improved for them. Screening tests may produce a shift to earlier stages at diagnosis without

any improvement in survival because of length and lead time bias effects.[31] Randomized controlled trials of screening mammography and fecal occult blood tests have demonstrated reductions in mortality accompanied by shifts in stage at diagnosis.[32,33] An analysis of survival experience was beyond the scope of our study.

Limitations

Stage at diagnosis is determined from information on extent of disease, which may be influenced by the diagnostic and therapeutic procedures used, as well as by the adequacy of provider record keeping. Any differences in such factors between HMOs and fee-for-service providers could influence our findings. The higher percentage of unstaged cases in fee-for-service suggests that reporting of extent of disease information was better for HMO enrollees. The high mortality of unstaged cases suggests possible underidentification of regional and distant cases, which would make our findings conservative regarding earlier diagnosis in HMOs. It is also possible, however, that the high mortality of unstaged cases may be due to the poorer underlying health involved in these cases rather than to greater spread of cancer at the time of diagnosis.

Our findings may not be generalizable to all HMOs with Medicare contracts. The HMO enrollees in our study were disproportionately enrolled in staff and group model HMOs. In addition, most HMO enrollees in San Francisco/Oakland and many enrollees in Hawaii were members of Kaiser Permanente; most in Seattle were members of the Group Health Cooperative of Puget Sound. Our database did not permit us to identify in which HMOs specific individuals were enrolled.

Policy Implications

Our findings suggest that coverage of preventive services may affect stage of cancer at diagnosis, which is strongly associated with survival and morbidity. Policymakers should consider a significant role for preventive services under health care reform. The Health Security Act, for example, proposes coverage for a significant level of preventive care, including Pap smears, screening mammograms, and clinician visits. Such services can be provided at reasonable cost, as evidenced by many HMOs that provide such services to Medicare enrollees and remain competitive with fee-for-service.

Stage at diagnosis can serve as a measure of access and quality of care in individual health plans. Under the Health Security Act, health alliances are expected to have a strong role in evaluating the quality of care in plans and making their findings available to consumers. Monitoring stage of cancer at diagnosis may be part of the alliances' evaluation function, particularly if Medicare comes under their purview. Monitoring stage may be somewhat easier than monitoring outcomes of care, which usually require complex case mix adjustments. Finally, health alliances should directly monitor access to and use of preventive services among participating health plans because access to such services is an important dimension of plan quality. □

Acknowledgments

We wish to thank Barry Bye for his assistance with statistical aspects of the study. We also appreciate the helpful comments of Carol Kosary and Karen Johnson, who reviewed earlier drafts of the paper. We thank Bruce Fireman of Kaiser Permanente and Stephen Taplin of the Group Health Cooperative of Puget Sound for providing information on the preventive services covered by their respective plans. We also thank Jennifer Stevens for her programming support and Florence Beckman and Charlotte Smith for their help in manuscript preparation.

Report Available on the Rapid Identification and Treatment of Acute Myocardial Infarction

Each year, about 1.25 million people in the United States experience a heart attack. Approximately 500 000 of these people die. It is thought that many of these deaths could be prevented by initiating medical help as soon as a heart attack is suspected. A new report by the National Heart Attack Alert Program (NHAAP), *Emergency Department: Rapid Identification and Treatment of Patients with Acute Myocardial Infarction,* discusses the scientific basis for early care and makes a number of recommendations for reducing emergency department delays in the identification and treatment of heart attack patients.

The report concentrates on the emergency department's contribution to overall time until treatment for acute myocardial infarction (AMI). It describes the scientific basis for decreasing the time from the onset of symptoms to treatment and then specifically addresses impediments to rapid care in the emergency department. The report proposes changes in processes that can reduce delays at each point and presents an AMI time-to-treatment flow sheet for tracking these critical AMI timepoints. The report encourages all departments responsible for acute care to coordinate and establish protocols to ensure rapid identification and treatment of AMI patients. Finally, the report challenges emergency departments to implement a system of continuous quality improvement to identify and reduce delays in the treatment of AMI patients.

The NHAAP was launched by the National Heart, Lung, and Blood Institute in June 1991 to promote the rapid identification and treatment of individuals with symptoms and signs of AMI. The overall goal of the program is to reduce AMI-related morbidity and mortality. The NHAAP Coordinating Committee—consisting of representatives from 40 national professional, scientific, governmental, and voluntary organizations (including APHA)—was formed to help guide the program.

Acutely Injured Patients with Trauma in Massachusetts: Differences in Care and Mortality, by Insurance Status

ABSTRACT

Objectives. This study was designed to determine whether resource use and mortality differed by insurance status for patients with acute trauma.

Methods. All adults emergently hospitalized in Massachusetts during 1990 with acute trauma (n = 15 008) were examined.

Results. After adjustment for confounders, uninsured patients were as likely to receive care in an intensive care unit as were patients with private insurance (odds ratio [OR] = 0.97, 95% confidence interval [CI] = 0.85, 1.11) but were less likely to undergo an operative procedure (OR = 0.68, 95% CI = 0.63, 0.74) or physical therapy (OR = 0.61, 95% CI = 0.57, 0.67) and were more likely to die in a hospital (OR = 2.15, 95% CI = 1.44, 3.19). Compared with patients with private insurance, those with Medicaid were less likely to receive an operative procedure (0.85, 0.75–0.97), were equally likely to receive care in an intensive care unit (OR = 1.05, 95% CI = 0.86, 1.30) or physical therapy (OR = 0.90, 95% CI = 0.79, 1.02), and were no more likely to die (OR = 1.28, 95% CI = 0.69, 2.39).

Conclusions. These results suggest that the uninsured receive less trauma-related care and have a higher mortality rate. The excess mortality in uninsured patients may be avoided if their resource use is increased to that of insured patients. (*Am J Public Health.* 1994;84:1605–1608)

Jennifer S. Haas, MD, MSPH, and Lee Goldman, MD, MPH

Introduction

Trauma is the fourth leading cause of death in the United States,[1] and it results in substantial morbidity. The annual cost of traumatic injuries is estimated to be more than $100 billion.[2] Some data suggest that 30% of trauma-related deaths may be prevented by appropriate prehospital and in-hospital care.[3,4]

Although previous work has demonstrated that the uninsured[5–8] are less likely to receive certain health care services, these studies have usually examined elective procedures or ambulatory services for which differences in rates of use may reflect patients' preferences. In addition, it has been difficult to control for differences in disease severity for chronic medical problems.[9] Finally, differences in procedure rates may not be associated with differences in health outcomes. Because of these limitations, no conclusions can be drawn as to the appropriateness of the observed variation.

To address whether lower rates of resource use by uninsured patients are associated with worse health outcomes, we studied patients with acute trauma. Since these patients are acutely injured, the relationship between in-hospital care and mortality may be more direct than for chronic health problems. Also, patients' preferences are less likely to explain differences in the use of procedures. Furthermore, the severity of injury can be measured reliably for patients with traumatic injuries in administrative data sets. The goal of this study was to examine whether resource use and mortality differed by insurance status for patients hospitalized with acute trauma.

Methods

Data

Discharge abstracts for all Massachusetts residents 15 to 64 years of age emergently hospitalized in a nonfederal, acute care hospital in Massachusetts during fiscal year 1990 were obtained from the Massachusetts Health Data Consortium. *International Classification of Diseases, Ninth Revision, Clinical Modification* (ICD-9-CM)[10] codes were used to indicate diagnoses and procedures. A maximum of 10 diagnosis and 10 procedure codes were listed for each patient. Of the 94 acute care hospitals in Massachusetts with trauma discharges in 1990, 9 were designated as level 1 trauma centers. Hospitals located in Boston, Cambridge, Springfield, Worcester, Lowell, or New Bedford were considered to be in an urban area. All of the level 1 trauma centers were located in an urban area.

Patients with a principal diagnosis code indicating major traumatic injury (ICD-9-CM codes 800 to 959), excluding those whose codes indicated the late effects of trauma (codes 905 to 909) or a foreign body (codes 930 to 939), were included in this study. Abstracts that indicated a transfer from another hospital were excluded to avoid analyzing multiple abstracts for the same patient.

Variables

Insurance status. Patients were categorized into three groups: (1) uninsured (self-pay or free care), (2) Medicaid, and (3) private insurance (Blue Cross/Blue Shield, commercial payers, and prepaid health plans).

TABLE 2—Adjusted Odds Ratios (95% Confidence Intervals) for Admission to a Level 1 Trauma Center or a Hospital Located in an Urban Area, by Payer

Payer	Admission to a Level 1 Trauma Center	Admission to a Hospital in an Urban Area
Uninsured	1.51 (1.39, 1.64)	1.45 (1.34, 1.57)
Medicaid	1.32 (1.15, 1.51)	1.35 (1.18, 1.54)
Private	1.0 ...	1.0 ...

Note. Odds ratios were adjusted for age, sex, race, Injury Severity Score, and comorbidity.

Resource use and in-hospital mortality. Measures of resource use that can be reliably identified in discharge abstracts include whether a patient has had an operative procedure, has been cared for in an intensive care unit, or has received physical therapy. These measures of resource use also have "face validity" (i.e., each is generally believed to improve health outcomes). A patient was considered to have undergone an operative procedure or physical therapy if the corresponding charge was noted or to have had an intensive care unit stay if a stay of at least 1 day in a medical, surgical, or cardiac intensive care unit was indicated. In-hospital mortality was defined as a discharge disposition of expired.

Race, severity of injury, comorbidity, and mechanism of injury. Patients were characterized into two racial groups, White and non-White (African American, Latino, Asian, other). The Abbreviated Injury Scale,[11] which assesses the severity of injury of each body region and is the most widely accepted injury severity measure based on anatomic injury,[12] was used to measure severity of injury. ICD-9-CM diagnosis codes were converted into Abbreviated Injury Scale scores by means of a validated algorithm.[13] The Injury Severity Score, which summarizes the Abbreviated Injury Scale scores of the three most severely injured body regions and has been associated with mortality from trauma,[14–16] was used to categorize overall severity of injury.

Conditions that have previously been shown to affect mortality in patients with trauma were analyzed,[17] including secondary diagnosis codes for cirrhosis (ICD-9-CM code 571), congenital coagulopathy (codes 286 and 287, excluding 286.6 and 287.4), ischemic heart disease (codes 410 to 414), chronic obstructive pulmonary disease (codes 490 to 496), and diabetes (code 250). Patients with at least one of these codes were defined as having a comorbid condition.

Information on mechanism of injury was available for 4873 patients (32.5%). Mechanism of injury was categorized as a gunshot wound (ICD-9-CM code E922, E955, E965, E970, or E985), a stab wound (code E920, E956, E966, E974, or E986), a fall (codes E880 to E888), a burn (codes 940 to 949), or a motor vehicle accident (codes E810 to E829). Patients with a diagnosis code indicating a gunshot wound or a stab wound were defined as having a penetrating injury.

Data Analysis

Differences in severity of injury (Injury Severity Score) between payer groups were analyzed with analysis of variance. Logistic regression analyses[18] were used to examine the relationship between payer and each marker of trauma-related care and mortality while adjusting for possible confounders, including age, sex, race, Injury Severity Score, and comorbidity. The same approach was used, in subgroup analyses, to examine patients with severe injuries (Injury Severity Score greater than 12), patients admitted to a hospital located in an urban area, and patients admitted to a level 1 trauma center. For the subgroup of patients with information about mechanism of injury, models that also controlled for penetrating vs nonpenetrating injury were examined.

Results

Most patients hospitalized with acute trauma in Massachusetts were White and privately insured (Table 1). The mean Injury Severity Score was 12.4. For example, the most common principal diagnosis associated with an Injury Severity Score of 12 was a concussion associated with a loss of consciousness. Of the 7120 patients (47%) who underwent an operative procedure, 5719 (81%) did so within the first 24 hours of hospitalization. The mean Injury Severity Scores were 12.4 for patients with private insurance, 12.8 for those with Medicaid, and 12.3 for the uninsured ($P = .20$).

The Injury Severity Score was significantly associated with resource use and in-hospital mortality. The mean Injury Severity Score for patients who underwent an operative procedure was 13.9, in comparison with 11.0 for those who did not ($P < .001$). For patients with an intensive care unit stay, the mean score was 22.4, in comparison with 11.0 for patients without such a stay ($P < .001$); for patients who received physical therapy, the mean score was 13.8, in comparison with 11.4 for those who did not ($P < .001$). The mean injury severity score for patients who died in the hospital was 41.8 in comparison with 12.0 for those patients who survived ($P < .001$).

Overall, 7111 patients (47%) received care in a hospital located in an urban area, and 4779 (32%) received care in a level 1 trauma center. Patients who were uninsured or covered by Medicaid were more likely to receive care in an urban hospital or in a level 1 trauma center after adjustment for age, race, injury severity score, and comorbidity (Table 2).

For the subgroup of patients with a known mechanism of injury, the Injury Severity Score for patients with a penetrating injury was not quite significantly

different than that for patients with other types of trauma (13.2 and 12.5, respectively, $P = .06$). The uninsured were more likely than patients with private insurance to have a penetrating injury (32.5% vs 10.6%, $P < .001$). After adjustment for Injury Severity Score, patients with a penetrating injury were more likely to die in the hospital (odds ratio [OR] = 2.46, 95% confidence interval [CI] = 1.36, 4.43).

After adjustment for age, sex, race, severity of injury, and comorbidity, patients who were uninsured, on average, received fewer resources and had higher rates of mortality than patients with private insurance (Table 3). Although patients with Medicaid were less likely to undergo an operative procedure than patients with private insurance, they were just as likely to receive care in an intensive care unit or to receive physical therapy, and they were not significantly more likely to die in the hospital.

Since patients who die early in their hospital stay may not have a full "opportunity" to receive trauma-related care, the analyses were repeated after excluding patients who died within the first 48 hours of hospitalization. After these patients were excluded, resource use was similar in magnitude and significance to that presented in Table 3.

In general, the patterns of trauma-related care and mortality were similar in subgroups of patients who were admitted to level 1 trauma centers, who were admitted to a hospital located in an urban area, who had severe injuries, or who had a known mechanism of injury as in the overall population (Table 4).

TABLE 3—Adjusted Odds Ratios (95% Confidence Intervals) for Trauma-Related Care and In-Hospital Mortality, by Payer

Payer	Use of an Intensive Care Unit	Operative Procedure	Physical Therapy	In-Hospital Mortality
Uninsured	0.97 (0.85, 1.11)	0.68 (0.63, 0.74)	0.61 (0.57, 0.67)	2.15 (1.44, 3.19)
Medicaid	1.05 (0.86, 1.30)	0.85 (0.75, 0.97)	0.90 (0.79, 1.02)	1.28 (0.69, 2.39)
Private	1.0 ...	1.0 ...	1.0 ...	1.0 ...

Note. Odds ratios were adjusted for age, sex, race, Injury Severity Score, and comorbidity.

TABLE 4—Adjusted Odds Ratios (95% Confidence Intervals) for Trauma-Related Care and In-Hospital Mortality, by Payer, for Selected Patient Subgroups

Note. Odds ratios were adjusted for age, sex, race, Injury Severity Score, and comorbidity.
[a]Injury Severity Score greater than 12.
[b]Models for patients with a known mechanism of injury were adjusted for age, sex, race, Injury Severity Score, comorbidity, and mechanism of injury (penetrating vs nonpenetrating injury).

Discussion

This study suggests that there are differences in resource use and mortality by insurance status for patients with acute trauma even after adjustment for the severity of the injury. Given the acute nature of these conditions, such differences seem unlikely to be explained by patients' preferences. The observed differences in resource use and mortality occurred among patients with severe injuries as well as those cared for in the most well-equipped trauma centers. Taken together, these data raise the possibility that the excess mortality experienced by the uninsured may be avoided if their use of resources is increased to match that of insured patients. While health insurance may be a proxy for other socioeconomic factors, patients with Medicaid had outcomes that were more comparable to those of patients with private insurance, suggesting that the presence of health insurance conveys improved access to trauma-related care.

We examined three markers of trauma-related care that were available in hospital discharge abstract data. We chose the use of care in an intensive care unit and the use of an operative procedure as measures of trauma-related care because these interventions commonly are urgent or emergent. The finding that 81% of patients who received an operative procedure underwent surgery within 24 hours of admission supports that surgery was usually an urgent intervention. Although physical therapy is not emergent, it is central to the rehabilitation of patients with injuries.[19] The consistency of the observed differences in care across various subgroups suggests that the uninsured truly receive fewer resources.

Our results extend prior analyses of variation in care by payer in several ways. Although other studies have demonstrated differences in the use of resources by payer,[5-8] these studies usually have not been able to address the appropriateness of the observed variation. Hadley et al.[6] found higher rates of in-hospital mortality and lower rates of expensive inpatient procedures among uninsured vs privately insured adults, although these differences largely involved elective procedures

Braveman et al.[20] found that, among newborns with medical problems, those without insurance had shorter hospital stays than those with private insurance. Finally, Ayanian et al.[21] found that, among women with breast cancer, the uninsured presented with more advanced disease and had shorter survival, perhaps related to diminished access to medical care. We chose to examine trauma-related care because the interventions are emergent or urgent and, therefore, the link between care and mortality is more compelling.

There are several potential explanations of our findings. Because of the high costs associated with trauma care, some hospitals may treat the uninsured less aggressively. Several hospitals have stopped providing trauma care because of operating deficits.[22] The observed differences may reflect an effort to conserve costs among patients who potentially cannot pay.

Although we controlled for severity of injury using a validated algorithm, our data set does not include any physiologic data. It is possible that unmeasured differences in severity of injury explain the observed differences in resource use and mortality by insurance status. The Injury Severity Score may underestimate the severity of injury for patients with penetrating injuries. In the subgroup of patients with information about mechanism of injury, those who were uninsured were more likely to have a penetrating injury, and a penetrating injury was associated with a greater likelihood of death after Injury Severity Score was controlled. Although the ICD-9-CM system allows for the classification of mechanism of injury with its E codes, these codes were not recorded for most patients. For the subgroup of patients with information about the mechanism of injury, controlling for this information did not change the differences in resource use or mortality by payer. Similarly, our data set contains limited clinical data. It is possible that unmeasured differences in clinical circumstance explain the observed differences in resource use and mortality.

There are also several less plausible explanations of our findings. First, differences in the likelihood of hospitalization among patients with trauma might account for the observed treatment differences among patients who reached the hospital. However, if the uninsured were more likely to be admitted to the hospital and therefore less in need of trauma-related care, their mortality rates should be lower. Second, the uninsured were more likely to receive care in inner-city hospitals; these hospitals may be overcrowded,[23,24] and their resources may be more limited. However, the observed differences persisted after we controlled for hospital location.

An observational study cannot conclude that there is a causal relationship between the observed differences in trauma-related care and mortality. This study examined only hospital-based care. Differences in prehospital care would also affect mortality. Our data do not include individuals who died before reaching the hospital or who died in the emergency department.

In conclusion, among patients with acute trauma, those who were uninsured were less likely to receive several measures of trauma-related care and were more likely to suffer in-hospital mortality than were those with private insurance. If the use of fewer resources is contributing to the higher mortality rate for the uninsured, then an increase in resource use would narrow the mortality differences. Since trauma is the leading cause of death among young adults, future investigations should consider how to reduce the disparities in the allocation of trauma-related care and how to measure the effect of such efforts on mortality and other health-related outcomes. □

Comparing Hospitals That Perform Coronary Artery Bypass Surgery: The Effect of Outcome Measures and Data Sources

Arthur J. Hartz, MD, PhD, and Evelyn M. Kuhn, PhD

ABSTRACT

Objectives. The relative quality of hospital care often is judged by comparing risk-adjusted rates of adverse outcomes. This study evaluated whether hospital quality comparisons are affected by the choice of outcome and the use of administrative data instead of clinical data.

Methods. The data were collected from 2687 coronary artery bypass surgery patients from 17 hospitals. All patients were on Medicare. For 10 hospitals with 94 to 713 patients, risk-adjusted outcomes for death, major complications, and any complications were derived from a clinically rich database and an administrative database.

Results. The correlations between adjusted hospital rankings derived from the clinical and administrative databases were not significant: .48 for mortality, .21 for major complications, and −.14 for any complication. When only the clinical database was used, the correlation between risk-adjusted hospital rankings for mortality and major complications was .77 ($P < .01$) and the correlation between major complications and any complication was −.45.

Conclusions. These results suggest assessing quality of care by the use of administrative data may not be adequate and that quality assessment by the use of clinical data may depend greatly on the outcome chosen. (*Am J Public Health.* 1994;84: 1609–1614)

Introduction

Quality of care at hospitals that perform coronary artery bypass surgery frequently is assessed by comparing patient outcomes.[1–8] Although quality of care may be best assessed by evaluating the process of care,[9,10] assessing quality of care by evaluating outcomes also is important.[11] The reasons for using outcomes to evaluate quality of care are the following: (1) the goal of medical care is outcome; (2) the optimal process of care is not known; (3) the actual process of care usually is not completely recorded; (4) information needed to determine the process of care is more difficult to abstract and, therefore, more expensive to collect than information needed to determine risk-adjusted outcome; and (5) outcome is characterized and analyzed more easily than process.

Despite the widespread interest in comparing outcomes to measure quality of care, there is no concensus on how outcomes should be measured. Measurement of quality of care depends on the choice of outcome, the source of data used to determine outcome, and the data that should be used to take into account patient risk when measuring outcome. An ideal measurement that depends on risk-adjusted quality of life[5–8] and that uses comprehensive risk factors collected concurrently is too expensive to obtain for most assessments of quality of care.

The most easily obtained and, therefore, most widely used source to determine risk-adjusted outcomes is the Uniform Bill 82 (UB82) discharge abstract. This abstract includes principal and secondary patient diagnoses, some complications, discharge status, and patient demographic information. The most reliable and important outcome coded on the discharge abstract is patient mortality. This outcome is commonly used to assess the quality of care provided by hospitals that perform coronary artery bypass surgery.[1–3] Using mortality as a measure of outcome, however, will not reveal many errors in care and requires large numbers of patients in order to obtain adequate comparison of hospitals. To obtain a more sensitive measure of care, some studies have used patient complications coded on the discharge abstract.[12–21] Unfortunately, the data available from the discharge abstract are limited; there are frequent coding errors in the principal diagnosis and comorbidities,[14,19,23] and there may be even greater errors made when complications are coded.[14] Therefore, both the outcomes and the risk-adjustment procedure obtained from the discharge abstract may be flawed.

Even when better data from special data abstractions are available,[20–25] there is still the issue of which outcomes should be evaluated. For example, comparisons of coronary artery bypass surgery patients have used such outcomes as mortality rate,[1–3] length of stay,[26] readmissions,[27] and complications of surgery.[4,28–31] The present study evaluated whether choice of outcome and data sources affect the assessment of quality of care given by hospitals that perform coronary artery bypass surgery.

Major complications[d]	377/637	59.2	377/468	80.6
Other bleeding	146/568	25.7	146/195	74.9
Infection	46/385	12.0	46/55	83.6
Any complication[e]	589/1139	51.7	589/707	83.3

[a]All patients who had a given complication are included in calculating the complication rate regardless of whether they survived.
[b]The proportion of complications indentified during clinical review that also were coded in the UB82 administrative data.
[c]The proportion of complications identified in the UB82 administrative data that also were coded during clinical review.
[d]Major complications includes any complication listed above plus mortality and extended hospital stay.
[e]Any complication includes any complication listed above plus mortality and extended hospital stay.

Methods

For this study, we derived six risk-adjusted outcome-based measures of quality of care from two data sources and assessed the relationship among the measures.

Data Sources

Data were obtained on Medicare patients from all Wisconsin hospitals that perform coronary artery bypass surgery and from one hospital outside Wisconsin. Data from charts of all bypass surgery patients from the Wisconsin hospitals were abstracted by the Wisconsin Peer Review Organization. These data were obtained from charts the organization reviewed from April 1990 to June 1991. The development of the data collection form and data collection procedure for the Wisconsin patients has been described previously.[4] Data from the hospital outside Wisconsin were abstracted by hospital medical records personnel for patients hospitalized in fiscal year 1990. The same data abstraction form and instructions were used for these patients and the Wisconsin patients. Data for the out-of-state hospital and Wisconsin hospitals were comparable in that the hospitals had the same relationship between clinical risk factors and clinical outcomes and the same relationship between outcomes from the clinical data and outcomes from the administrative data.

Data were collected on 2687 patients from 17 hospitals, 15 of which were not-for-profit and 5 of which were teaching hospitals. Thirteen of the hospitals had more than 300 beds. Because the purpose of this study was to compare hospital rankings on the basis of different measures of patient outcome, however, the assessed hospitals had to have sample sizes large enough to obtain relatively stable estimates of complication rates. For this reason, only those nine hospitals that had at least 100 patients (one hospital had only 94 patients) were considered individually. A composite hospital with more than 100 patients was formed from the remaining hospitals. Patients from one smaller hospital were excluded from the analysis. This hospital had a rate of nonfatal major complications of only 2.1% compared with 15.7% for the average hospital and 10.5% for the hospital with the second lowest rate of nonfatal complications. In addition, personnel at this hospital acknowledged significant problems with the content of their medical records. For these reasons, we considered the error rate for the data from this hospital unacceptable for our study. Excluding patients from this hospital reduced the number of patients to 2641.

Patient Outcomes

The data elements were obtained from computerized UB82 billing data and from a coronary artery bypass surgery–specific abstract for which data were collected manually. The UB82 billing data included the patient's age and sex, up to five diagnoses of comorbidities or complications, three procedures, admission and discharge dates, number of days in the intensive care unit, and whether the patient was discharged alive. The coronary artery bypass surgery–specific data included information on any of the following major adverse outcomes: death, periprocedure myocardial infarction, renal impairment, stroke, readmission to the intensive care unit, endocarditis, bowel bleeds or necrosis, pancreatitis, or a long hospital and intensive care unit stay. Definitions for these outcomes have been presented previously.[4] A patient who died or had any of these adverse outcomes was considered to have a sustained "major adverse outcome" based on the coronary artery bypass surgery abstract data. "Any adverse outcome" was defined as a major adverse outcome or any of the following: the patient was on a respirator for 48 hours or more, developed an infection, returned to surgery because of bleeding, or required six or more units of blood, platelets, or plasma.

Adverse outcomes derived from the UB82 data were combinations of the following: death, postoperative length of stay greater than the 95th percentile (28 days), a major complication coded in the UB82 data, and any complication coded in the UB82 data. The major complications coded in the UB82 data were central nervous system complications (9970), urinary or renal complications (9975), endocarditis (4219), pancreatitis (5570), and postoperative shock (9980). Additional codes used for any complication were infection or inflammatory reaction due to internal prosthetic device, implant, or graft (9966); postoperative infection (9985 or 9993); and hemorrhage or hematoma complicating a procedure (9981).

In combinations of adverse outcomes from either the coronary artery bypass surgery abstract or the UB82 abstract, we always included major adverse outcomes when less major adverse outcomes also were included (e.g., every combination that included renal impairment also included death, and every combination that included return to surgery also included death and renal impairment).

Methods to Adjust for Risk of Illness

Patient risk of illness was derived from information on the patient risk factors. The coronary artery bypass surgery abstract contained information on 35 patient risk factors that have been described previously.[4] Although ideally it is better to risk-adjust u ing only patient characteristics that are objectively identified and do not depend on physician judgment, physician management decisions sometimes provide patient information that is not present in the medical record or that is difficult for the nonspecialist to extract. We used physician decisions as proxy information for patient characteristics for two reasons: (1) to determine severely compromised cardiac function and (2) to characterize the anatomy of the coronary disease.

The patient's age and information on up to five diagnoses listed in the UB82 abstract were used to create the Charlson index, a risk of illness measure that has been used in many previous studies and has been found to be related to mortality rate for bypass surgery patients.[32-34] This index was tested for an association with patient outcome and used to risk-adjust hospital outcome. The Charlson index derived in this study may not have characterized a patient's risk of illness as well as a Charlson index derived when more diagnoses are available.

The other method we used to determine a patient's risk of illness for this study was logistic regression analysis. Stepwise logistic regression was used as described previously[4] to identify risk factors that have an independent association with a given outcome. We derived separate equations from risk factors limited to data elements from the UB82 abstract and from risk factors on the coronary artery bypass surgery abstract.

The risk of illness measure was used to derive a method to compare hospitals on the basis of patient outcome after taking into account patient risk. To calculate the relative odds of an adverse patient outcome at one hospital compared with all other hospitals, we used the logistic regression equation with an indicator variable for a given hospital. The relative odds of a complication for patients at a given hospital compared with patients in all other hospitals was e^b, where b is the regression coefficient of the indicator variable.[35]

Results

Patient characteristics and complication rates are shown in Table 1. Because the patients in the study were on Medicare, almost all were older than 64 years, and the mean age was 71. The average length of stay after the procedure was approximately 13 days. The most common major complications were mortality (8.0%), long length of stay in the hospital or intensive care unit (6.6%) and postoperative myocardial infarction (6.5%).

The relationship between the complications identified by the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM), codes and complications identified from the UB82 abstract are shown in Table 2. With the exception of stroke, fewer than 26% of the complications identified on the coronary artery bypass surgery abstract were coded on the UB82 abstract. The UB82 abstract was moderately sensitive (50% to 60%) at identifying the existence of major complications or any complication primarily because the sensitivity of the form for detecting mortality or long stay was considered to be 100%. To detect at least one of the other major complications, the sensitivity was only 21.7%.

One reason for the low sensitivity of the UB82 abstract in identifying complications other than mortality or long stay was that there was room for only five diagnoses and complications on the form used by most hospitals. To determine whether space limitations contributed to the low sensitivity, we examined the data from UB82 abstracts from one hospital that listed nine diagnoses on its form. For this hospital, the sensitivity of the UB82 abstract for detecting major complications other than mortality increased from 21.7% with five diagnoses to 38.4% with nine diagnoses.

The right column of Table 2—"Clinical/Administrative"—shows the percentage of complications coded on the UB82 abstracts that were identified on the coronary artery bypass surgery abstracts. These percentages were much greater than the percentages under "Administrative/Clinical"; for major complications, infection, and any complications, the "Clinical/Administrative" percentage were greater than 80%. The percentage was not higher because of errors or limitations of the coronary artery bypass surgery abstract and, more important, because the ICD-9-CM code is not specific (i.e., the same code refers to many complications, both major and minor).

The rates for each adverse outcome of the 10 hospitals are shown in Table 3. The hospitals are ordered by the rate of major complications, which varied significantly among the hospitals ($P = .02$ by the chi-square test for contingency tables). There was nearly a twofold variation in the major complication rate, and two of the hospitals had rates that differed significantly at the $P < .05$ level from the rates for all other patients combined. There also was substantial variation in the rates for any complication ($P < .0001$); five hospitals had rates of any complication that differed from the rates of other hospitals at the $P < .05$ level of significance. Some rankings were similar for different outcomes, and some rankings differed greatly. One hospital had the lowest rate of major complications (a ranking of 1) and the highest rate of any complication (a ranking of 10) even though 56% of the patients who had any complication had a major complication.

Hospital rankings adjusted for patient risk of illness are shown in Table 4. The hospitals are listed in the same order as in Table 3 to make it possible to compare unadjusted and adjusted rankings. Some hospitals were substantially affected by the adjustment procedure for some outcomes. The most extreme example is that the hospital with the ninth highest unadjusted morality rate had the lowest rate after adjusting for the factors in the coronary artery bypass surgery abstract. Another example is that the hospital with the highest unadjusted rate of major complications had the fifth highest adjusted risk of major complications.

The correlations among the risk-adjusted outcome-based measures of quality of care are shown in Table 5. The risk-adjusted outcomes from the UB82 abstracts had nonsignificant correlations with the risk-adjusted outcomes from the coronary artery bypass surgery abstracts. Two of the risk-adjusted outcomes derived from the coronary artery bypass surgery abstracts were significantly correlated—death and major complications ($r = .77$, $P < .01$)—but the risk of all complications was not significantly correlated with these two risks.

The last row of Table 5 shows the correlation between corresponding unadjusted and adjusted outcome measures. Mortality and the rate of major complications were substantially affected by adjustment for variables in the coronary artery bypass surgery abstracts. Adjusting for the information from the UB82 abstracts made little difference in hospital assessment (i.e., all of the correlations were greater than .90). Correlations between unadjusted rates and rates adjusted with the Charlson index were greater than .97.

Table 5 does not show the correlation between the risk-adjusted mortality rate and the rate of major nonfatal complications. The correlation for these rates was .31 for all hospitals and .79, after eliminating one hospital. Using a bootstrap procedure to test the significance of the maximum correlation obtained by choosing 9 of 10 points, we found that the P value for a correlation of .79 was .035.

Discussion

The findings of this study suggest that the results of outcome-based assessments of quality of care at hospitals that perform coronary artery bypass surgery varies depending on the source of data and the outcome measure used. Neither the outcome measures nor the risk factors from the UB82 abstracts were precise or accurate enough to derive quality measures that reflected those derived from the coronary artery bypass surgery abstracts. Risk adjustment for mortality was not adequate with the UB82 abstract data, and complications frequently were not recorded in these data. Even when as many as nine ICD-9-CM codes were captured, fewer than 40% of the complications from the coronary artery bypass surgery abstracts were captured with the UB82 abstracts. The codes that were recorded frequently were not specific enough to distinguish major from minor complications.

As found in previous mortality studies,[4,12] risk adjustment with UB82 in our study data was not nearly as effective as risk adjustment with coronary artery bypass surgery abstract data. Risk adjustment did not affect rankings for most hospitals because most hospitals had patients at a similar level of risk; however, risk adjustment did make a substantial difference for some hospitals.

Choice of outcome also affected measurement of quality of care. Although there seemed to be a relationship at most hospitals between the risk-adjusted rates of mortality and major complications, there was no statistical evidence that hospital rates of any complication were associated with hospital rates of major complications or mortality.

The major advantage of this study was that it employed a common, comprehensive data set from several hospitals. The major disadvantage was that neither the sample sizes per hospital nor the number of hospitals was large. With larger sample sizes, we would have been able to estimate more precisely the strength of associations between the different measures of quality of care. A second disadvantage is that we did not have any standard measure of quality of care, such as postdischarge quality-adjusted survival. Without such a standard, it was not possible to determine which outcome measures provided the best information about the quality of care. A third disadvantage is that we were not able to evaluate whether the quality of data or the types of missing data differed by hospital type.

Recent outcome-based measures of quality of care have been sophisticated and varied.[1-21,25-31] Hospital comparisons, however, generally are restricted to one outcome. Our results suggest that performance across outcomes is not uniform. It is possible that optimum measurement of quality of care may require the examination of several outcomes. Each outcome-based measure of quality of care may reflect different aspects of the process of care, and hospitals should be informed about their performance regarding all aspects of care that can be evaluated adequately. □

Call for Abstracts for International Symposium on Epidemiology in Occupational Health

A call for abstracts has been issued for the 11th International Symposium on Epidemiology in Occupational Health, which will be held September 5–8, 1995, in Noordwijkerhout, near Amsterdam, the Netherlands. The symposium, which will offer an international platform for the exchange of knowledge on occupational epidemiology, will include plenary and parallel sessions related to the following themes:

- Occupational epidemiology methods
- Occupational surveillance methods, evaluation, and ethical aspects
- Occupational diseases, injuries, and cancer
- Neurological, reproductive, and developmental effects
- Respiratory diseases
- Musculoskeletal disorders
- Work-related stress
- Exposure assessment in occupational epidemiology
- Biomarkers
- Communicable diseases at work

The symposium is being organized by the Department of Epidemiology and Public Health and Department of Air Quality at the Agricultural University, Wageningen, and the Department of Public Health at Erasmus University, Rotterdam, on behalf of the Scientific Committee on Occupational Epidemiology of the International Committee on Occupational Health.

The deadline for submission of abstracts is *January 31, 1995.* For more information, contact the conference secretariat: Susan Peelen, MSc, Department of Epidemiology and Public Health, PO Box 238, 6700 AE Wageningen, the Netherlands; tel +31 8370 84124; fax +31 8370 82782. E-mail: susan.peelen;@medew.hegl.wau.nl.

Rates, Patterns, Causes, and Costs of Hospitalization of Nursing Home Residents: A Population-Based Study

William H. Barker, MD, James G. Zimmer, MD, W. Jackson Hall, PhD, Brian C. Ruff, Charlene B. Freundlich, and Gerald M. Eggert, PhD

ABSTRACT

Objectives. Hospitalization of nursing home residents is a growing, poorly defined problem. The purposes of this study were to define rates, patterns, costs, and outcomes of hospitalizations from nursing homes and to consider implications for reducing this problem as part of health care reform.

Methods. Communitywide nursing home utilization review and hospital discharge data were used to define retrospectively a cohort of 2120 patients newly admitted to nursing homes; these patients were followed for 2 years to identify all hospitalizations. Resident characteristics were analyzed for predictors of hospitalization. Charges and outcomes were compared with hospitalization of community-dwelling elders.

Results. Hospitalization rates were strikingly higher for intermediate vs skilled levels of care (566 and 346 per 1000 resident years, respectively). Approximately 40% of all hospitalizations occurred within 3 months of admission. No strong predictors were identified. Length of stay, charges, and mortality rates were higher than for hospitalizations from the community.

Conclusions. Hospitalizations from nursing homes are not easily predicted but may in large part be prevented through health care reforms that integrate acute and long-term care. (*Am J Public Health.* 1994;84:1615–1620)

Introduction

The elderly population experiences not only disproportionately high rates of admission to hospitals and nursing homes but high rates of transfer between these settings. Transfer from hospitals to nursing homes has been extensively studied during the past 2 decades.[1,2] However, while there have been studies involving selected institutions,[3–8] there have been virtually no population-based studies of transfers from nursing homes to hospitals in the United States. The magnitude of the problem is substantial: the 1977 and 1985 National Nursing Home Surveys reported, respectively, 339 500 and 430 200 discharges to hospitals, resulting in estimated annual ratios of 242 and 265 hospitalizations per 1000 long-term care beds.[9,10] Such hospitalizations are costly[11] and potentially detrimental to frail elderly people[12,13]; hence, they are important to health services research and policymaking.

The dearth of population-based studies of hospitalization from nursing homes may be ascribed in part to the lack of data systems that link hospital and nursing home use. This, in turn, is a reflection of the historic separation between financing and organization of acute and long-term care in the United States.[14,15] The present study used unique computerized data sets available on all nursing home admissions and hospitalizations in the early 1980s for a defined geopolitical area. The purposes were to determine rates, predictors, causes, and costs of hospitalization of nursing home residents and to consider strategies for reducing these occurrences as part of national health care reform.

Materials and Methods

Setting

The setting for the study, Monroe County, New York, is an urban-suburban-rural jurisdiction centered on the city of Rochester. Table 1 compares selected characteristics for Monroe County and the country at large in the early 1980s. The ratio of general hospital beds per 1000 persons was somewhat smaller in Monroe County, while the ratio of nursing home beds per 1000 elderly persons (those more than 65 years of age) was slightly higher. At the time of this study, approximately 30% and 70% of nursing home beds were classified as intermediate care and skilled care, respectively, in both Monroe County and the country as a whole.[16] Specifically, there were 33 licensed nursing homes in Monroe County in 1982, all of which included skilled care beds (approximately 3600) and 9 of which included intermediate care beds (approximately 1400). (Intermediate and skilled care facilities are defined in the Appendix, and the differences between the two are described. With passage of the 1987 Omnibus Budget Reconciliation Act nursing home reform legislation, the skilled nursing facility and intermediate care

William H. Barker, James G. Zimmer, and Charlene B. Freundlich are with the Department of Community and Preventive Medicine, and W. facility designations have been replaced by the single designation of residential health care facility for all nursing home beds.[17])

Design and Data

A retrospective cohort design was used in which all patients newly admitted to nursing homes in the county during a single calendar year (1982) were identified and followed for 2 years or until death to ascertain and analyze all episodes of transfer to acute hospitals.

The study population consisted of 2120 nursing home patients admitted between January 1 and December 31, 1982 (1700 and 420, respectively, to skilled and intermediate levels of care). The average length of stay during the 2-year period of follow-up was 402 days for the cohort of skilled nursing facility residents and 376 days for the cohort of intermediate care facility residents.

The principal source for identifying and characterizing the study cohort and for ascertaining hospitalizations was the computerized utilization review file maintained by the Monroe County Long Term Care Program, one of the first community-wide long-term care case management agencies in the country. The program was responsible for tracking all nursing home admissions and discharges in the county between 1977 and 1985.[18] Physical function and mental and behavioral status data were based on the Disability Measurement Scale (DMS-1) utilization review scale in routine use in nursing homes in New York State in the 1970s and early 1980s.[19] Baseline chronic medical conditions for cohort members were obtained by hand from utilization review forms maintained by the Genesee Valley Medical Foundation, a nonprofit agency that conducts, under contract, utilization reviews in nursing homes in Monroe County. These conditions were classified into broad disease categories developed for an earlier study of nursing home utilization in Monroe County.[20]

Discharge diagnoses, lengths of stay, and charges and outcomes of hospitalizations were obtained from the uniform billing forms routinely used by all hospitals in New York State. These forms, obtained through cooperative arrangements with all eight acute care hospitals in the county, accounted for all hospitalizations in the cohort. For comparison with hospitalizations among the community-dwelling population more than 65 years of age, computerized uniform billing form data were obtained from the Rochester Area Hospital Experimental Payment Program, which was in effect during the 1980s.[21] (The uniform billing form provides total dollar charges but not costs; therefore, we report comparative charges data. Because the hospitalizations from nursing homes and from the community involve the same hospitals, the relation of costs to charges was presumed to be similar for the two groups.)

Analysis

Overall rates of hospitalization and rates per 1000 resident-years were computed. Analyses for predictors of hospitalization were conducted separately for skilled nursing facility and intermediate care facility cohorts. Univariate analyses (with chi-square tests for significance) were performed to determine associations between demographic, medical, and functional status characteristics present at admission to nursing home and subsequent hospitalization. Stepwise multiple logistic regression analyses were performed to determine combinations of predictors of hospitalization (including any interactions) among admission characteristics; analyses were repeated for prediction of multiple hospitalizations. Distribution of hospitalizations by principal discharge diagnosis, length of stay, charges, and status at discharge (dead or alive) were computed for all hospitalizations and for those within each of the three age subgroups: 65 through 74, 75 through 84, and 85+ years. These data were compared with information on hospitalizations of people more than 65 years old living in the community.

Results

A total of 892 hospitalizations occurred among the 2120 subjects (a computed rate of 387 hospitalizations per 1000 resident-years). Table 2 summarizes overall frequency and rates of hospitalization for the skilled nursing facility and intermediate care facility cohorts. The percentages of residents experiencing at least one hospitalization during the 2-year follow-up period differed markedly by

level of care: 26.5% for skilled nursing facility residents vs 41.7% for intermediate care facility residents. Some 8% of skilled nursing facility and 13% of intermediate care facility residents experienced multiple discharges to a hospital. After adjustment for time at risk, the difference between the two cohorts persisted, with rates of 346 (skilled nursing facilities) and 566 (intermediate care facilities) total hospitalizations per 1000 resident-years. Cumulative percentages of hospitalization over time, for those ever hospitalized, are shown in Table 3. Graphs (not shown) were quite similar for the two groups, with the skilled nursing facility curve rising slightly faster (i.e., having a slightly heavier concentration of hospitalizations in the first 60 days). Approximately 40% of hospitalizations occurred within the first 90 days, and roughly three quarters within the first year, in each group.

*$P < .05$.

Predictors

Tables 4 and 5 examine the association between individual baseline admission characteristics and subsequent hospitalization. For each category of baseline characteristics, hospitalization rates were compared within the skilled nursing facility and intermediate care facility cohorts. Location from which subjects were initially admitted to a nursing home, whether hospital, home, or another institution, was not associated with greater or lesser risk of subsequent hospitalization in either cohort. There was also little difference within the cohorts in risk of hospitalization among age groups, except for slightly lower percentages for the small number of residents less than 65 years of age. Men had higher rates than women in the skilled nursing facility cohort ($P < .05$). Residents with diabetes, gastrointestinal disease, or depression at the time of admission had somewhat higher risks of subsequent hospitalization in the skilled nursing facility cohort, while intermediate care facility residents with cancer, chronic obstructive pulmonary disease, seizure disorder, or depression had somewhat higher risks of hospitalization; however, chi-square tests comparing each of these rates with those among members of the respective cohorts with other baseline chronic conditions showed P values greater than .10. Within the skilled nursing facility cohort, residents in several large nursing homes with full-time medical staffs experienced lower subsequent rates of hospitalization ($P < .05$). Such relationships were not observed among the intermediate care facility subjects in the same institutions. Analyses by baseline functional status (Table 5), restricted to skilled nursing facility residents, revealed a lower rate of hospitalization for the small number who were totally bedbound ($P < .05$).

In summary, in the skilled nursing facilities, only male gender and absence of on-site medical staff were statistically significant predictors of hospitalization, and even then the differences in rates were not large. Being bedbound was associated with a significant lowering of risk. Source of admission, age group, and chronic medical conditions were not significant. For the intermediate care facilities, there were no significant predictors.

TABLE 5—Percentage of Skilled Care Nursing Home Residents with One or More Hospitalizations during the 2-Year Follow-Up, by Selected Physical, Mental, and Behavior Functions

Functional Status	No. with Characteristic	% with Hospitalization

Note. Functional status, based on admission assessment data from the DMS-1 instrument,[19] was not analyzed for intermediate care facility residents because most were independent or minimally impaired in functions at the time of the admission assessment.

[a]1 = independent, unimpaired; 2 = partial dependence or impairment; 3 = total dependence or impairment.

[b]1 = no incontinence; 2 = intermittent incontinence; 3 = always incontinent; 4 = indwelling catheter.

*$P < .05$.

Stepwise multiple logistic regression analyses failed to reveal single characteristics or combinations of characteristics, including those listed in Tables 4 and 5, that were any more predictive of hospitalization than the limited associations found in univariate analyses. We were likewise unable to identify any combinations of characteristics predictive of (1) hospitalizations that occurred early vs later in the nursing home stay or (2) multiple hospitalizations.

Causes, Charges, and Outcomes

In Table 6, the most common principal discharge diagnosis groups are compared between hospitalizations that occurred among older persons in nursing homes (n = 808) and those living in the community (n = 24 891). Because the distributions by discharge diagnoses were very similar for hospitalizations from the intermediate care facility and skilled nursing facility cohorts, these data have been combined in the analysis. Noteworthy are the significantly greater proportions of cardiovascular and neoplastic disease and cataract surgery hospitalizations among community-dwelling elderly people and of pneumonia and hip fracture hospitalizations among nursing home residents. Overall average lengths of stay in the hospital were approximately 1 day longer (14.4 vs 13.2) and average charges slightly higher for elderly persons admitted from nursing homes than for those from the community (Table 7). These figures showed interesting reverse trends when analyzed for age subgroups, with the younger nursing home residents and the more elderly community-dwelling persons experiencing the longer and costlier hospitalizations within their respective populations. Within each age subgroup, a higher percentage of patients from nursing homes were dead at discharge from the hospital.

Discussion

A number of excellent literature reviews have focused on acute medical care problems of nursing home residents, with particular emphasis on transfers to acute hospitals.[22,23] The literature is composed largely of short-term studies conducted from the limited perspective of one or more selected hospitals, nursing homes, or patient subsets; thus, it is difficult to apply to an understanding of the problem from the perspective of a general population of nursing home residents. By contrast, the present study, using data available from two concurrent communitywide demonstrations,[18,21] reported rates and patterns of acute hospitalization over a 2-year period among a cohort of all patients newly admitted to nursing homes within a defined population. In brief, the study found a rate of hospitalization that was high relative to rates computed from National Nursing Home Surveys, concentrated within the first 3 months of admission to the nursing home, and most strongly associated with the level of care to which residents were assigned on admission. Within each of the two broad levels of care (skilled and intermediate), resident age, sex, medical conditions, and functional parameters at admission, as well as prior locus (home, hospital, other), were generally not strongly associated with risk of subsequent hospitalization, while the presence of on-site medical staff in large institutions was associated with a lower risk for skilled nursing facility residents. Finally, cost of care, as reflected in hospital charges, and mortality rates were somewhat higher, on average, for hospitalizations of nursing home residents than for hospitalizations of community-dwelling elderly people. How should these findings be interpreted, and what are the policy implications for health service delivery for nursing home residents?

The observed strikingly higher rate of hospitalization in the present study (387 per 1000 resident-years), in contrast with ratios derived from the 1977 and 1985 National Nursing Home Surveys data (242 and 265 per 1000 long-term beds per year), may in part reflect a regional tendency toward higher rates of use of acute hospitals by nursing home residents. Given the relatively low hospital bed to population ratio in Monroe County (Table 1) and the well-recognized overall lower rates of hospital admission in the county throughout the 1980s,[24] this is probably not a major factor. The more likely explanation lies in the different population frames of reference for the respective studies. The Monroe County study population, an admission cohort of nursing home residents, would include a higher percentage of relatively short-stay, potentially unstable subjects at higher risk of acute medical decline and transfer to hospital, while the National Nursing Home Surveys data, based in substantial part on a prevalent population of nursing home residents, would include a greater proportion of long-stay, more stable subjects.[25]

There are several possible reasons for the interesting, seemingly paradoxical finding of higher rates of hospitalization among people admitted to lower levels of nursing home care. A leading possibility is that the lesser degree of medical and nursing supervision for patients at lower levels of chronic care leads to a need to transfer unstable residents to hospitals more often than would be necessary from better staffed skilled nursing facilities (see Appendix). In addition, given the greater prevalence of compromising physical and mental disability among skilled care residents, it may be that heroic medical intervention, including transfer to a hospital in instances of acute illness, is withheld more often among these residents. The withholding of life-saving interventions, including hospitalizations, per the ex-

pressed wishes of older persons in nursing homes has been increasingly discussed and formalized in recent years.[26–28]

The failure to more fully identify individual characteristics or patterns of characteristics predictive of which nursing home residents are most at risk of hospitalization within either the skilled nursing facility or intermediate care facility level of care may be attributable to limitations in the utilization review data used in this study. While utilization review at admission is intended primarily for classifying residents by level of need for assistance with activities of daily living within the nursing home, it is readily acknowledged that baseline utilization review data on medical conditions may be incomplete and do not permit classification of conditions by medical severity,[29] which is clearly a most important factor in risk of hospitalization.[30]

Nursing home residents, like community-dwelling elderly persons,[31] had relatively high overall risks of hospitalization as well as rehospitalization. The somewhat higher average charges and mortality rates and higher proportion of respiratory infections and fractures involved in hospitalizations of those from the nursing home cohort in comparison with those from the community are similar to findings reported elsewhere.[3–6] Recognizing that many nursing home hospitalizations might be avoided by applying relatively unsophisticated acute services on site (e.g., intravenous antibiotics), various earlier studies have estimated that as many as 40% to 50% of these hospitalizations might be preventable.[8,32] Given the substantial costs and frequency of hospitalization of nursing home residents and evidence that these factors may be increasing since implementation of the Medicare Prospective Payment System,[2,22] reducing such hospitalizations becomes a serious policy consideration. (Hospital discharges from Monroe County nursing homes ranged between 900 and 1200 from 1986 to 1990 [L. Varricchio, Finger Lakes Health Systems Agency, written communication, August 1993].)

A number of cost-saving strategies for reducing hospitalizations from nursing homes without compromising quality of care have been demonstrated in recent years. These include employing geriatric nurse practitioners in nursing homes,[33,34] providing financial incentives for primary care physicians and nursing home staff to treat serious acute illnesses on site,[35] offering nursing home residents the opportunity to express their preference with regard to use of acute hospital services in the event of a life-threatening acute illness,[28] and, in larger institutions, establishing an "infirmary" unit for care of serious acute illnesses.[36]

Most of these strategies require modification of traditional staffing and reimbursement for clinical care in nursing homes.[14,37,38] Much neglected in the past, these needs have begun to be met in the form of the 1989 legislation authorizing Medicare reimbursement of nurse practitioners in nursing homes (Public Law 101-239) and the 1993 implementation of increased Medicare fees for physician services in nursing homes.[39] Although these are important enabling steps, it is not likely that reimbursement reform alone, in the absence of organizational reform, will achieve the full potential for reducing transfers from nursing homes to hospitals. In this regard, the proposed inclusion of long-term care in national health care reform[40,41] affords a unique opportunity to overcome our long and costly legacy of separation of the acute and chronic health service sectors, epitomized by frequent transfers of patients between nursing homes and hospitals. Such integration of the delivery system in Great Britain has resulted in far lower rates of hospitalization from long-term care institutions.[15] This approach has been emulated in other societies with comprehensive national health programs[42] and deserves high priority when considering the needs of older Americans as part of national health care reform. □

TABLE 6—Distribution of Hospitalizations of Persons 65 Years of Age or Older from Nursing Homes and from the Community, by Principal Discharge Diagnosis

Risk Factors for Delayed Immunization among Children in an HMO

ABSTRACT

Objectives. Improving the timely delivery of childhood immunizations has become a national imperative. This study aimed to identify nonfinancial predictors of delayed immunization among patients with good financial access to preventive care.

Methods. This prospective cohort study used telephone interviews and a computerized immunization tracking system to evaluate 13-month-old children (n = 530) in a regional group-model health maintenance organization.

Results. More than one third of parents interviewed did not know when the next immunization was due. Thirteen percent were late for the measles-mumps-rubella immunization, recommended at 15 months of age, by 90 days or more. Independent predictors of delayed immunization included having a larger number of children (odds ratio [OR] = 1.4, $P < .01$), not having a regular doctor (OR = 2.9, $P < .05$), not knowing when the shot was due (OR = 2.0, $P < .01$), and not worrying about the risks of shots (OR = 1.4, $P < .05$).

Conclusions. Financial access alone does not guarantee timely childhood immunization. In managed care settings, which may cover increasing numbers of children under health care reform, interventions are needed to better inform parents of when immunizations are due. (*Am J Public Health.* 1994;84:1621–1625)

Introduction

More than one third of US children have not been appropriately immunized by the second birthday.[1] Delayed immunization is a major public health problem that has been associated with measles epidemics in recent years.[2] Better financial access to preventive care is a necessary but not sufficient condition for timely immunization.[3–6]

Improving immunization delivery will require a better understanding of nonfinancial reasons for delay. Previous studies have not been able to prospectively evaluate parent beliefs while controlling for financial access.[7–9] In this prospective study of children with good financial access to preventive care, we evaluated (1) the rate of delayed immunization; (2) the influences of nonfinancial risk factors; and (3) the accuracy of existing computerized information as a basis for identifying high-risk children for advance outreach efforts.

Method

Study Design

Parents of 13-month-olds were interviewed by telephone. Each child was then followed for at least 5 months via a computerized immunization tracking system. The system was initiated at the Northern California Kaiser Permanente Medical Care Program (KPMCP) in the winter of 1991 and included any child immunized at any of 13 clinics on-line at the start of this study. The measles-mumps-rubella (MMR) immunization was used as the main outcome measure because it is the first immunization due in the second year of life, when children are most likely to miss immunizations. The immunization was considered delayed if given more than 90 days after the due date.[10,11]

Study Population

KPMCP is a group-model health maintenance organization (HMO) that covers approximately 700 000 children in a geographic region approximately 250 miles in diameter. Most members receive health insurance as an employment benefit. Immunizations are covered in full, although some members must copay up to $15 for well-child care visits.

Between March and July of 1992, 6696 children seen in the KPMCP clinics served by the immunization tracking system turned 13 months old. Telephone interviews were attempted with 831 randomly selected families. Families were ineligible if the parents did not speak English, Spanish, or Cantonese (n = 10); the telephone number was wrong or had been disconnected (n = 52); they reported not using KPMCP, usually because they had a second form of insurance coverage (n = 61); or the child experienced a gap in KPMCP insurance coverage between 13 and 18 months of age (n = 103).

Note. CI = confidence interval; NS = not significant.
[a]Numbers may not sum to 530 owing to missing values. No more than 3% of data in any category were missing, except for income, in which 8% of data were missing.
[b]Relative risk is expressed in comparison with the baseline categories: White, college graduate or more, more than $50 000 annual household income, one child, one parent employed, two-parent family, and more than 3 years' residence at current address.
[c]The chi-square test was used for categorical variables. The Wilcoxon rank-sum test was used for ordinal variables (father's education, annual household income, and number of children in family).
[d]For one-parent households, this variable was scored "yes" if the parent was employed.

Telephone Survey

A 15-minute, 33-question telephone survey was conducted in English, Spanish, or Cantonese by six experienced interviewers. It covered demographic characteristics, family organization, health care system variables, and vaccine knowledge and attitudes. Family organization questions included numbers of children and adults in the household and how many years the family had lived at its present address. Health care system questions covered experiences at the last visit for well-child care and whether the child had a regular doctor or nurse-practitioner at KPMCP.

For vaccine knowledge and attitudes, parents were asked when they expected the child's next well-child checkup, when they expected the next shot, whether the child or any of the family's other children had ever had a worrisome reaction to a shot, and whether the child had ever been more than a month late for a shot. Parents were asked how much they worried about the risks of shots, how much they would worry if the child were not up to date on shots, and whether the parent had ever hesitated to have the child get a shot. (A copy of the survey instrument is available from the authors.)

A follow-up survey was conducted for children without an immunization tracking system record of an MMR by 18 months of age. For 13 of these children, the parent reported and chart review confirmed that the MMR immunization had been given, usually at a KPMCP facility that was not yet part of the immunization tracking system. The computerized data were corrected prior to analysis.

Statistical Analysis

In the bivariate analysis the chi-square test (with Yates' continuity correction for 2×2 tables) was used for categorical variables, the Wilcoxon rank-sum test was used for ordinal variables, and the Spearman correlation coefficient was used for associations between ordinal variables. Multivariate analysis was performed with logistic regression procedures in SAS (SAS Institute, Inc, Cary, NC).

Results

Of the 605 eligible families, 530 (88%) completed interviews. Sixty-eight were unreachable after repeated attempts, and 7 declined to be interviewed.

Predictor Variables

Table 1 shows the demographic and family organization characteristics of the study population. In terms of health care system variables, almost all parents (96%) said their child had a regular primary care provider at KPMCP. Most (53%) had no copayment for well-child visits; 43% paid between $1 and $5. Forty-five percent of parents had missed or rescheduled work to bring their child to his or her last well-child visit. A plurality of parents (45%) had had the last well-child visit scheduled between 1 and 2 months in advance, 51% had waited less than 15 minutes to see the primary care provider, and 59% had spent between 1 and 2 hours on the round trip to the appointment, including transit time.

Table 2 shows parental knowledge and attitudes about immunization. Parents were asked when they expected their child's next well-child appointment and next shot. Answers that fell before the child's 16-month birthday were scored as correct. It is noteworthy that 36% of the parents in this study did not know when their child's next shot was due; this answer was highly correlated with not knowing when the next well-child visit was due ($P < .001$).

Delayed Immunization Rates and Predictors of Delay

Two thirds of the children in the study group received their MMR vaccinations within 30 days of the due date. However, 16% were late for the vaccination by 60 days or more, and 13% were late by 90 days or more. The rate of delayed immunization at 90 days was higher among ineligible and unreachable families (21%) than among the study group.

The baseline telephone interview was not intended to change behavior, but it could have influenced study group families to seek more timely immunization. After children with gaps in KPMCP insurance between 13 and 18 months of age (for whom the immunization tracking system might have incomplete records) were excluded, there were 530 families in the study group, 645 in the attempted interview group, and 4448 in the control group not selected for interview attempts. The study group had a lower rate of delayed immunization (13%) than the control group (19%; $P < .001$), but this comparison is biased by the inability to exclude ineligible and unreachable patients from the control group. The rate of delayed immunization among all 645 families in the attempted interview group (16%) was lower but not significantly different from that of the control group ($P = .08$).

Univariate analysis of predictors. Black race was correlated with delayed immunization (Table 1): 21% of Black children, compared with 10% of White children, were late by 90 days or more ($P < .05$). Income, education, and language spoken at home were not significantly associated with immunization delay. Families with more children were at higher risk for delayed immunization ($P < .01$).

Unexpectedly, parents who reported having had the previous appointment scheduled more than 2 months in advance had lower rates of delayed immunization than parents who had the appointment scheduled sooner ($P < .05$). Having had the previous appointment scheduled farther in advance may indicate better organizational skills on the part of parents rather than a longer wait for appointments. The amount of copayment was not associated with delayed immunization.

Most attitudes toward vaccines were not associated with delayed immunization (Table 2). Paradoxically, the more the parent worried about the risks of vaccines, the lower the likelihood of delayed immunization ($P < .05$). Not knowing when the next shot was due ($P < .001$) was strongly correlated with delayed immunization. It should be noted that 15-month-olds are eligible to receive the MMR immunization on time even if they have been late for previous immunizations. Despite this fact, having been late for a previous shot by the parent's report was also a strong predictor of delayed MMR immunization ($P < .001$).

Multivariate analysis of predictors. Variables associated with delayed immunization at a level of $P < .10$ were included in a logistic regression model (Table 3). Families with more children, those who did not identify a regular doctor, those who did not know when the shot was due, and those who worried less about the risks of shots were at significantly increased risk for delayed immunization. After adjusting for these other factors, Black race was no longer a significant predictor of delayed immunization. Having been late for a previous immunization was excluded from the final model because its similarity to the outcome of interest tended to reduce the explanatory power of other predictors. However, when this variable was included it was significant (adjusted odds ratio = 3.0, 95% confidence interval = 1.6, 5.7, $P < .001$), and the other significant predictors remained significant with the exception of not identifying a regular doctor ($P = .07$).

TABLE 2—Parental Knowledge and Attitudes and Their Associations with Delayed Immunization of 13-Month-Olds (n = 530): Northern California Kaiser Permanente Medical Care Program, 1992

	No. (%)	Relative Risk of Delayed Immunization[a]	95% CI	P[b]
Late for a previous shot by a month or more (by parent's report)				
Yes	99 (19)	2.6	1.7, 4.1	<.001
No	421 (80)	...	...	...
Don't know	10 (2)	...	...	...
Reason for being late for previous shot				
Child was sick	31 (31)	...	...	...
Appointment was unavailable	13 (13)	...	...	...
Too busy	7 (7)	...	...	...
Didn't know it was due	3 (3)	...	...	...
Forgot	3 (3)	...	...	...
Other[c]	42 (42)	...	...	...
Did not know when next shot was due	189 (36)	2.2	1.4, 3.3	<.001
Did not know when next well-child visit was due	149 (28)	1.6	1.0, 2.5	.06
Ever hesitated to have a previous shot	33 (6)	1.7	0.9, 3.5	NS
Ever had a vaccine reaction that caused worry	60 (11)	0.8	0.3, 1.7	NS
Amount parent worries about risks of shots				.02
A great deal	35 (7)	...	...	...
A moderate amount	111 (21)	1.0	0.3, 3.6	...
A little	215 (41)	1.4	0.4, 4.3	...
Not at all	169 (32)	2.0	0.7, 6.4	...
Amount parent would worry if child were late for a vaccine				NS
A great deal	314 (60)	1.5	0.8, 2.8	...
A moderate amount	126 (24)	...	...	...
A little	65 (12)	2.1	1.0, 4.5	...
Not at all	23 (4)	2.0	0.7, 5.7	...

Note. CI = confidence interval; NS = not significant.

[a]Relative risk is expressed in relation to the baseline categories: not late for a previous shot, knew when next shot or well-child visit was due, never hesitated to have a previous shot, never had a vaccine reaction that caused worry, worries a great deal about risks of shots, and would worry a moderate amount if child were late for a vaccine.

[b]The chi-square test was used for categorical variables. The Wilcoxon rank-sum test was used for ordinal variables (amount parent worries about risks of shots, amount parent would worry if child were late for a vaccine).

[c]Other reasons parents gave for being late for shots included family emergencies, lapses in health insurance coverage, the regular doctor's going on vacation, and rescheduling of appointments.

TABLE 3—Logistic Regression Analysis of Predictors of a Delay of 90 Days or More in Measles-Mumps-Rubella Immunization: Northern California Kaiser Permanente Medical Care Program, 1992

	Adjusted Odds Ratio	95% Confidence Interval	P
Black race	2.0	0.9, 4.3	NS
Asian race	1.6	0.8, 3.3	NS
Latino race/ethnicity	1.1	0.5, 3.4	NS
Number of children in family	1.4	1.1, 1.8	.007
How far in advance previous appointment was made[a]	0.7	0.5, 1.0	NS
No regular doctor by parent's report	2.9	1.0, 8.6	.05
Didn't know when next shot was due	2.0	1.2, 3.5	.01
Amount parent worries about risks of shots[b]	0.7	0.6, 0.8	.03

[a]Ordinal variable. 1 = less than 1 month, 2 = 1 to 2 months, 3 = more than 2 months. Thus, having made the last appointment farther in advance was associated with a lower risk of delayed immunization.
[b]Ordinal variable. 1 = not at all, 2 = a little, 3 = a moderate amount, 4 = a great deal. Thus, worrying more about the risks of vaccines was associated with lower rates of delayed immunization.

Risk Prediction Based on Computerized Data

Two variables available from traditional computerized databases—not having a regular physician assigned and not having made at least three well-child visits during the first 7 months of life—were used as predictors of delayed MMR immunization. Having either of these risk factors identified children who had delayed immunization with a sensitivity of 41% and a specificity of 75%. Thus, fewer than half of the children who would be late for the MMR immunization could be identified in advance by means of information from existing databases.

Follow-Up Survey

Of the 69 families identified by the immunization tracking system as 90 or more days late for the MMR, 43 had follow-up interviews. Two children were reportedly immunized outside KPMCP, one in Mexico and one at a public clinic. Nine parents said a shot had been given at KPMCP, but there was no record of these shots in the written chart or on the tracking system. Three children had received the MMR after 18 months of age.

Twenty-nine parents said their child had not received a vaccination in the past 3 months or that they did not know. Sixteen of these said they had been aware the shot was due and 12 said they had not. The main reason cited for delay was not knowing the shot was due (n = 10), illness of the child (n = 2), and being too busy or forgetting (n = 4). Eight parents cited other reasons, including difficulty in taking time off from work and expecting reminders in the mail.

Discussion

This study shows that financial access to preventive care does not guarantee timely childhood immunization. Although prompt immunization rates are higher among KPMCP children than among the general population, one in eight children enrolled in KPMCP was at least 3 months late for the MMR vaccination.

This study suggests that managed care settings should attempt to better inform parents of when immunizations are due. More than one third of parents of 13-month-olds in this study did not know when their child's next shot was due, and these families were twice as likely as others to be late for the MMR. These findings support two interventions: (1) improving the written information handed out to parents at visits to highlight when immunizations are due and (2) reminding families when immunizations are due via letters or telephone calls.

Advance outreach efforts in managed care settings may be difficult; variables from existing computerized databases could not accurately predict which children would have delayed immunization in this study. However, immunization tracking systems should at least enable providers to promptly remind families who have already missed an immunization. An automated telephone reminder system has proven cost-effective when used with an immunization tracking system in the general population.[12]

This study underscores the importance of continuity of health care, in that families who did not identify a regular doctor or nurse-practitioner were almost three times as likely to be late for the MMR immunization. This result supports evidence from other studies, which suggests that the ability of patients to identify a primary care provider enhances the quality of health care.[13-16] The study did not find an association between copayment amounts and delayed immunization; previous studies have reached divided conclusions on this question.[17,18]

The relatively high immunization rates in this population may be explained, at least in part, by good financial access to a comprehensive health care system that covered immunizations. This study is unique in controlling for financial access while prospectively evaluating nonfinancial predictors. Education, income, and language were not associated with delayed immunization. Families with more children were more likely to have delayed immunization; this finding was similar to that of a previous study.[8] In the general population, children of minority races are at higher risk for delayed immunization.[19] In the present study, Black race was associated with delayed immunization, but the association was not statistically significant after other potentially mediating variables, such as knowledge of when the shot was due, ability to identify a regular doctor, and family size, were controlled.

We found no association between most parental attitudes toward vaccination and subsequent delay in immunization. Unexpectedly, parents who worried more about the risks of shots were actually less likely than others to be late, perhaps because their worrying reflected a generalized anxiety about health that could be associated with a higher likelihood of seeking preventive services.

This study included families of diverse races and educational levels. However, it was limited by the ineligibility of 27% and the unreachability of 9% of the patients selected for attempted interviews. Hard-to-contact respondents may have been more likely to be non-White[20] or to have recently moved or changed insurance plans. This could have biased the study against identifying these characteristics as predictors of delayed immunization. The finding that 24% of the children experienced gaps in KPMCP insurance between 13 and 18 months of age demonstrates the challenge of devel-

oping integrated immunization tracking systems, which will need to coordinate records as families change providers and insurance plans.

We conclude that delays in childhood immunization and gaps in parent understanding of immunization requirements occur even among families with good financial access to health care. Financing reform should improve access to immunizations for some children. Among children with good financial coverage, more work is needed on interventions to better inform parents of when immunizations are due. □

Ninth National Conference on Chronic Disease Prevention and Control

The Centers for Disease Control and Prevention, Association of State and Territorial Health Officials, and Association of State and Territorial Chronic Disease Program Directors will cosponsor the Ninth National Conference on Chronic Disease Prevention and Control, which will be held December 7–9, 1994, in Washington, DC. The conference is open to the public. There is no registration fee. This year's theme is "Chronic Disease Prevention and Control and the New Public Health."

The conference will provide participants with a forum for sharing information, skills, knowledge, and experiences related to chronic disease prevention and control. The conference will emphasize interactions among federal, state, and local health departments; voluntary health agencies; and professional organizations. Presentations will be given in plenary, invited, abstract, poster, training, and workshop sessions.

Additional information is available from the National Center for Chronic Disease Prevention and Health Promotion, CDC, Mailstop K-30, 4770 Buford Hwy NE, Atlanta, GA 30341-3724; tel (404) 488-5390; fax (404) 488-5974.

Presumptive Eligibility for Pregnant Medicaid Enrollees: Its Effects on Prenatal Care and Perinatal Outcome

Joyce M. Piper, DrPH, Edward F. Mitchel, Jr, MS, and Wayne A. Ray, PhD

ABSTRACT

Objectives. "Presumptive eligibility" permits pregnant prospective Medicaid enrollees to obtain services during the application period. The purpose of this study was to assess the effects of presumptive eligibility on the receipt of prenatal care and the occurrence of low-birthweight births and neonatal, perinatal, and infant mortality.

Methods. Outcome rates for pregnant women who enrolled in Tennessee Medicaid in the 6-month period before presumptive eligibility was enacted were compared with those obtained for pregnant women who enrolled in the 6-month period after presumptive eligibility had been in effect for 5 months.

Results. Women in the "after" group were 40% more likely to enroll and 30% more likely to obtain prenatal care in the first trimester. They were 300% more likely to fill a prescription for prenatal vitamins in the first trimester and 16% more likely to have begun prenatal care before the third trimester. However, they were similar to those enrolling in the "before" time period in terms of the occurrence of adverse perinatal outcomes.

Conclusions. When barriers to prenatal care, including bureaucratic ones, are removed, low-income women will seek care earlier and more frequently. (*Am J Public Health.* 1994;84: 1626–1630)

Introduction

Expanded Medicaid eligibility for pregnant women is based on the premise that early, regular prenatal care reduces adverse pregnancy outcomes.[1] Low-income women, who are more likely to start pregnancy with unmet health care needs, have been shown to derive particular benefit from prenatal care.[2,3] Counseling about diet, smoking cessation, and drug avoidance is an important component of prenatal care and its impact may be greatest if counseling is received early.[4] Early prenatal vitamin supplementation may also be particularly important for low-income women.[5]

"Presumptive eligibility" is a term used in federal legislation permitting states to allow certain providers (such as local health departments, community health centers, and hospitals) to determine temporary eligibility and to provide prenatal care during the formal processing period.[6] In Tennessee, selected providers may issue temporary (45-day) Medicaid cards to pregnant clients who appear to qualify for Medicaid. These cards can then be used to obtain outpatient services, including prenatal care, while the permanent Medicaid enrollment application is being processed.

The same federal legislation that permitted states to issue presumptive eligibility also authorized states to drop the "assets test" for pregnant clients, thus further allowing states to simplify the complex and lengthy application process and accompanying documentation. Prior to these legislative changes, a pregnant prospective Medicaid enrollee would be required to apply for enrollment, supply detailed assets information, and have her application evaluated. Only after completion of this process, which often required several visits to the application office, could the applicant schedule a prenatal visit with a health care provider or clinic willing to accept Medicaid patients. As a result, it might be impossible for her to use Medicaid to obtain early (first trimester) prenatal care.

As part of a series of investigations designed to assess the effects on pregnancy outcomes of Tennessee Medicaid expansions for pregnant women,[7,8] we examined the effects of presumptive eligibility. Initially authorized by the Omnibus Budget Reconciliation Act of 1986, both presumptive eligibility and elimination of the assets test are options chosen by a majority of states.[9] Some states have opted to expedite Medicaid enrollment for pregnant women in other ways, such as permitting mail-in applications and shortening the form length.[9]

In Tennessee, Medicaid coverage of pregnant women was expanded to include those living at 100% of the federal poverty level on July 1, 1987; the assets test was eliminated on March 1, 1988; and presumptive eligibility went into effect on February 1, 1989. At that time, more than half the states did not have presumptive eligibility.[10] Therefore, our findings regarding presumptive eligibility and pregnancy outcome may predict subsequent changes in other states and the country as a whole.

At the time of the study, all authors were with the Preventive Medicine Department, Vanderbilt University, Nashville, Tenn. Dr Piper died after the study was completed.

FIGURE 1—Time line showing "before" ("preintervention") and "after" ("postintervention") study time periods in relation to Tennessee Medicaid regulatory changes for pregnant women.

Methods

Study Population

We studied outcome rates for pregnant women who enrolled in Tennessee Medicaid in the 6-month period before presumptive eligibility was enacted (August 1, 1988, through January 31, 1989) and for pregnant women who enrolled in Medicaid in the 6-month period after presumptive eligibility had been in effect for 5 months (July 1, 1989, through December 31, 1989). As shown in Figure 1, during both of these periods Tennessee Medicaid eligibility was restricted to those with countable income (no assets test) at or below 100% of the federal poverty level.

Because our purpose was to evaluate a regulatory change that affected only pregnant women who were not enrolled in Medicaid, we removed any woman from the study population who was already enrolled in Medicaid before the start of the index pregnancy. These high-risk women included women with chronic medical conditions, very young women who qualified for Medicaid as children themselves, women who became pregnant during the postpartum coverage period of a previous pregnancy, and very poor women who received Aid to Families with Dependent Children. The study population was further limited to women who were either White or Black and who had delivered a single live infant with a recorded birthweight of 500 to 6000 g or a stillborn infant.

Data Sources

Data were obtained from Tennessee birth, fetal death, and death certificates and Tennessee Medicaid files. Data available from birth and fetal death certificates included personal identifiers of the mother and infant (or fetus); demographic characteristics, including maternal age, race, marital status, and place of residence and number of years of education of both parents; and medical characteristics of the mother and infant (or fetus), including month of pregnancy prenatal care began, date of the last menstrual period, mother's parity, plurality of the birth, and birthweight. Data pertaining to demographics, the timing of initiation of care, and the adequacy of care were taken from birth and fetal death certificates. Approximately 1% of birth and fetal death certificates from both periods studied were excluded because of missing data. Death certificate information included personal identifiers, demographic characteristics of the decedent, and cause of death. Linked birth and death certificate files were used to ascertain mortality rates. Medicaid data files included personal identifiers, demographic characteristics, beginning and ending dates of Medicaid coverage, hospital and outpatient diagnoses and procedures, and outpatient prescription medications, including when the prescription was filled.[11] During the study period, prenatal vitamins were included in the Medicaid formulary. Data on the use of prenatal vitamins were taken from Medicaid files, as were data related to the timing of enrollment.

TABLE 1—Characteristics (%) of Pregnant Women Who Enrolled in Tennessee Medicaid before and after Enactment of Presumptive Eligibility

	"After" Group (n = 9702)	"Before" Group (n = 9495)	*P*[a]

Linkage of Medicaid and Vital Records

We identified births to women in the study population through the computerized linkage of Medicaid, birth certificate, infant death certificate, and fetal death certificate files.[12] The linkage between the Medicaid files and vital records was required to ensure complete ascertainment of births among Medicaid-enrolled women and to obtain information on the women and their offspring that was available only from vital records. Because we did not require that the child be enrolled in Medicaid to classify the mother as enrolled at the time of birth, we included in the Medicaid group those women whose deliveries resulted in stillbirth or whose newborns died before they could be enrolled in Medicaid.[12] Consideration of only those births for which there is Medicaid information on the mother, delivery, and child may lead to serious

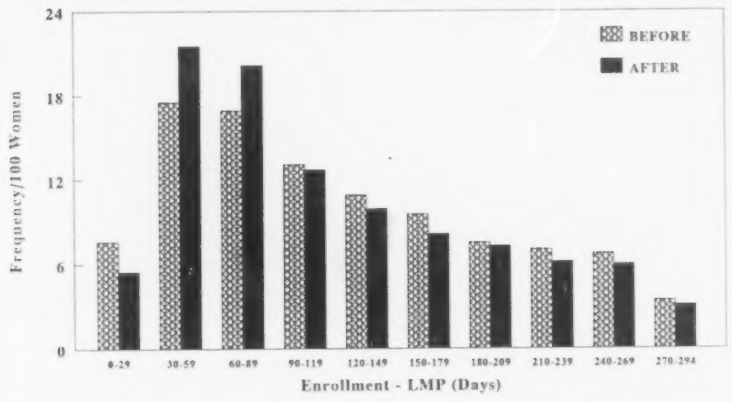

FIGURE 2—Time in pregnancy (days since last menstrual period [LMP]) Medicaid enrollment began for women who enrolled in Tennessee Medicaid in the study periods before and after presumptive eligibility was enacted.

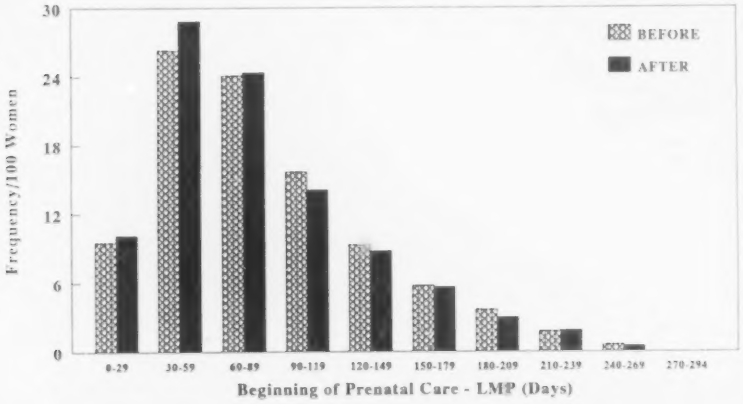

FIGURE 3—Time in pregnancy (days since last menstrual period [LMP]) prenatal care began for women who enrolled in Tennessee Medicaid in the study periods before and after presumptive eligibility was enacted.

underascertainment of fetal, perinatal, and neonatal mortality rates.[12]

Definitions

The start of pregnancy was defined as the date of the last menstrual period as reported on the birth or fetal death certificate. If the day of the month of the last menstrual period was missing, the 15th was imputed. For approximately 15% of linked deliveries, the last menstrual period either was missing month and/or year or, for live births, resulted in implausible gestational lengths (<140 days or >294 days). In these cases, the date of last menstrual period was estimated by using the median length of gestation for infants of similar race and birthweight. Reportable fetal deaths for which the date of the last menstrual period was missing were not studied. Reportable fetal deaths are fetal deaths for which a Tennessee Fetal Death Certificate must be filed. They include deaths of fetuses weighing 500 g or more or, in the absence of weight, of 20 or more weeks' completed gestation. All Tennessee counties were classified as either urban (within a metropolitan statistical area) or rural (outside metropolitan statistical areas) as designated by the Bureau of the Census in cooperation with the Tennessee State Planning Office.[13] Parity was defined as the total number of live births and fetal deaths, including the current birth. High parity density was defined as the third or later birth to women younger than 25 years and the fourth or later birth to women aged 25 through 29 years. All other births except the first represent low parity density. The first trimester was defined as the 90-day period after the date of the last menstrual period as reported on the birth certificate. Thus, the third trimester represents the 90-day period beginning 180 days after the date of the last menstrual period. The use of prenatal care is reported in terms of trimester of pregnancy in which prenatal care began (no first-trimester care, no care, or care begun in the third trimester), and inadequate care is measured by the Kessner Index.[14] However, birth certificate data may not be sufficiently accurate to rely on this or any of the indices of the adequacy of prenatal care.[15] Birthweights of less than 2500 g were classified as very low (<1500 g) or moderately low (1500–2499 g). Perinatal mortality rate was defined as the number of reportable fetal deaths plus the number of neonatal deaths divided by the total number of live births and reportable fetal deaths. Prenatal vitamins were defined as any vitamin or mineral product included in the Medicaid formulary.

Statistical Analyses

The chi-square test was used to test the null hypothesis (i.e., that there was no difference in the characteristics of Medicaid enrollees in the two time periods). The *t* test was used to test the hypothesis that presumptive eligibility shortens the time from initial Medicaid application to receipt of prenatal care. Three different aspects of timing were examined: (1) when Medicaid enrollment began, relative to the last menstrual period; (2) when prenatal care began, relative to the last menstrual period; and (3) when the woman initially filled a prescription for prenatal vitamins, relative to the last menstrual period.

To more fully assess the effects of individual and combined maternal factors in the comparison groups, we calculated odds ratios for measures of the attainment of prenatal care and adverse pregnancy outcome from the unconditional regression model obtained from the BMDP logistic regression program.[16] Models were constructed with terms that

included the study period and the maternal characteristics of age group, race, marital status, educational attainment, parity density, and urban/rural county of residence.

Results

In the 6-month "before" time period (August 1, 1988, through January 31, 1989), there were 9495 women who enrolled in Medicaid after their last menstrual period who otherwise met our study criteria. In the 6-month "after" time period (July 1, 1989, through December 31, 1989), there were 9702 women who enrolled in Medicaid after their last menstrual period who otherwise met our study criteria. Of these, 3995 women (41.2%) enrolled in Medicaid with presumptive eligibility.

Study subjects in the "before" and "after" time periods were similar in terms of race, marital status, educational level, parity, and county of residence (Table 1). However, slightly more women older than 29 years enrolled in the "after" than in the "before" time period (9.7% vs 8.5%; $P = .02$).

Figure 2 compares the distributions of the time in pregnancy when Medicaid enrollment began for the two study groups. Pregnant women who enrolled in Medicaid in the "after" time period (mean = 3.40 months, SE = 2.45) did so earlier in pregnancy than those in the "before" time period (mean = 3.59 months, SE = 2.53) ($t = 5.27, P = .00002$).

Figure 3 compares the distributions of the time in pregnancy when prenatal care began for the two study groups. When those who received no care (3.25% in the "after" group and 3.54% in the "before" group) were excluded, women in the "after" group began prenatal care slightly earlier (mean = 3.25 months, SE = 1.68) than those in the "before" group (mean = 3.34 months, SE = 1.70) ($t = 4.16, P = .00002$).

Figure 4 compares the distributions of the time in pregnancy when the woman initially filled a prescription for prenatal vitamins for the two study groups. When those who did not fill a prescription for prenatal vitamins at any time in the index pregnancy (45.46% in the "after" group and 54.60% in the "before" group) were excluded, women in the "after" group filled prescriptions for prenatal vitamins earlier in gestation (mean = 5.41 months, SE = 2.03) than women in the "before" group (mean = 6.09 months, SE = 1.86) ($t = 16.80, P = .00009$).

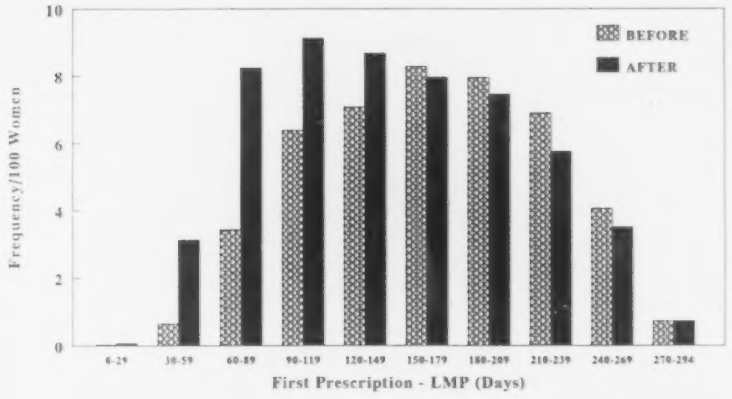

FIGURE 4—Time in pregnancy (days since last menstrual period [LMP]) initial prescription for prenatal vitamins and minerals was filled for women who enrolled in Tennessee Medicaid in the study periods before and after presumptive eligibility was enacted.

TABLE 2—Rates of Prenatal Care Use (%) for Pregnant Women Who Enrolled in Tennessee Medicaid before and after Enactment of Presumptive Eligibility

	"After" Group	"Before" Group	Adjusted Odds Ratio[a]	95% Confidence Interval
Enrolled in Medicaid in first trimester	50.2	42.0	1.40	1.32, 1.48
Prenatal care began in first trimester	64.2	60.9	1.30	1.17, 1.45
Prenatal vitamins in first trimester	11.4	4.1	3.06	2.71, 3.46
Had adequate or intermediate prenatal care	87.4	85.9	1.14	1.04, 1.24
Prenatal care began before third trimester	93.0	92.0	1.16	1.03, 1.29

Note. The variables in the model include maternal age group, race, education level, marital status, parity density, and county of residence.
[a]Reference category: the "before" time period.

TABLE 3—Rates (per 1000) of Adverse Pregnancy Outcomes for Pregnant Women Who Enrolled in Tennessee Medicaid before and after Enactment of Presumptive Eligibility

	"After" Group	"Before" Group	Adjusted Odds Ratio[a]	95% Confidence Interval
Moderately low birthweight (1500–2499 g)	70.1	75.4	0.91	0.81, 1.01
Very low birthweight (< 1500 g)	14.0	16.1	0.86	0.68, 1.09
Neonatal mortality	4.2	4.7	0.91	0.60, 1.40
Perinatal mortality	8.9	7.9	1.15	0.84, 1.57
Infant mortality	9.5	8.9	1.06	0.79, 1.43

Note. The variables in the model include maternal age group, race, education level, marital status, parity density, and county of residence.
[a]Reference category: the "before" time period.

Table 2 presents rates of prenatal care and adjusted odds ratios for the two study groups. Women in the "after" group were 40% more likely to enroll in the first trimester and 30% more likely to obtain prenatal care in the first trimester. They were more than three times as likely to fill a prescription for prenatal vitamins in the first trimester than were women in the "before" group. They were also more likely to have adequate or intermediate care as measured by the Kessner Index and to have begun prenatal care before the third trimester of pregnancy. However, there was no difference in adverse outcomes of pregnancy between the two groups (Table 3).

Discussion

We compared two groups of pregnant women: those who enrolled in Medicaid at a time when eligibility was limited to those whose countable income was at or below 100% of the federal poverty level and those who enrolled in Medicaid at a time when eligibility was similarly limited but enrollment was facilitated by presumptive eligibility. Presumptive eligibility increased the proportion of women who enrolled in Medicaid during the first trimester and was successful in reducing the proportion of women who failed to begin prenatal care in the first trimester, the proportion who obtained inadequate care (too few visits for gestational age at birth), and the proportion who delayed obtaining care until the third trimester or failed to get any care at all. It also led to a dramatic increase in first-trimester Medicaid prescriptions for prenatal vitamins, although this finding must be tempered by our lack of data on non-Medicaid prescriptions as well as the secular trend in general prenatal vitamin use.

Given the improved receipt of prenatal care that occurred with the implementation of presumptive eligibility, why did we not observe corresponding reductions in the rates of moderately low birthweight, very low birthweight, and perinatal, neonatal, and infant mortality? According to an Institute of Medicine report, prenatal care improves pregnancy outcome by first reducing the occurrence of low-birthweight deliveries.[1] This reduction is, in turn, reflected in improved survival of neonates. Such results may become evident in studies with larger numbers of participants or longer times from intervention to assessment than were the case in the present study, or adjustments in the content of prenatal care may be required.

Several factors limit these findings. First, the analysis is restricted to a single state, Tennessee. The situation may be different in other states. Second, there may be confounding by secular trend; that is, there may be a tendency independent of the Medicaid expansions for women to obtain prenatal care earlier and more regularly over time. The pre- and postintervention nature of our study design limits our ability to detect such a trend. Third, our data sources (vital records and Medicaid enrollment files) may not contain sufficient information to detect important outcome changes. For example, these sources do not contain information on the content and quality of prenatal care. Fourth, subsequent Medicaid regulatory changes, namely enactment of expanded eligibility to pregnant women living at 150% of the federal poverty level on January 1, 1990, permitted only a short time from enactment of presumptive eligibility to our evaluation of its effects. It is possible that as clients and health care providers become more familiar with presumptive eligibility, it will have a much greater effect on perinatal outcome.

We believe that this analysis of presumptive eligibility is the first study of Medicaid expansion to demonstrate a consistent improvement in process, if not outcome. When barriers to prenatal care, including bureaucratic ones, are removed, low-income women will seek care earlier and more frequently. Other recent studies of expanded prenatal services for pregnant women have reported either very limited[17] or no success[18] in terms of improved receipt of care and reduction of adverse outcomes. These studies, along with the data presented here, suggest that universal health care coverage for pregnant women will improve the receipt of prenatal care. Whether prenatal care alone is sufficient to improve the perinatal outcome for low-income women remains to be demonstrated. □

The Danger of Applying Uniform Clinical Policies across Populations: The Case of Breast Cancer in American Indians

ABSTRACT

Objectives. This study examined the implications of annual screening mammography for cost and mortality in American Indian populations with differing baseline breast cancer rates.

Methods. A decision tree compared annual screening mammography and screening clinical breast examination with referral for diagnostic mammography when appropriate The decision tree was constructed to examine the effect of different baseline cancer rates, stage at diagnosis, and stage-specific survival. Outcomes included 5-year relative survival, deaths prevented at 5 years, cost per death prevented, and total costs.

Results. The findings suggest that the total cost of breast cancer is 3.6 times higher with the screening mammography program but results in a 27.9% reduction in breast cancer deaths over the first 5 years of the program. Both costs and deaths prevented are sensitive to the incidence of breast cancer in the population and are less favorable in the range of incidence seen in American Indians.

Conclusions. The cost and impact of a given strategy for cancer screening vary among communities with different disease incidence, stage at diagnosis, and stage-specific survival, as seen in American Indian populations. (*Am J Public Health.* 1994;84:1631–1636)

Introduction

Over the last 5 years, a great deal of attention has been given to developing national clinical policies as a strategy to reduce practice variation, improve patient outcomes, and reduce the costs of health care.[1-3] Community-based studies in chronic disease are highly valued and used to inform clinical policy decisions, and they often influence clinical policy for populations well beyond those in which the original studies were conducted. While some attention is given to the effect of sociocultural differences on health and care-seeking behaviors, less attention is paid to the generalizability of results across populations with differing baseline disease rates.

The difficulty in developing a rational policy for breast cancer screening for the different populations served by the Indian Health Service (IHS) illustrates a universal but poorly appreciated dilemma. The IHS provides health and medical care services to more than a million American Indians and Alaska Natives in the continental United States and Alaska and allocates a finite resource base across a broad range of strategies for improving the health status of these populations. Allocation decisions involve trading off the potential benefits of a particular strategy against others for the same or competing health problems. To complicate clinical policy decisions for the IHS, there is considerable variation in the occurrence of different health problems among different American Indian and Alaska Native populations, as well as variation in the probability of success for the potential strategies to deal with these problems. Moreover, there is often variation in the cost of a given strategy in its application to the vastly different socioeconomic and political environments of American Indian and Alaska Native communities.

Screening for breast cancer presents an important clinical policy question for the IHS. The incidence of breast cancer in American Indian and Alaska Native populations is believed to vary from 20% to nearly 70% of the rate in the US general population.[4-9] There is evidence that American Indian and Alaska Native women with breast cancer are diagnosed at a more advanced stage of disease and that stage-specific survival is worse than for non-Indian women.[10] This study used formal decision analysis to examine the cost and outcome implications of a given clinical policy for screening mammography when applied to communities with differing breast cancer rates, stage at diagnosis, and stage-specific survival experiences.

Methods

A decision tree was constructed to compare two strategies for breast cancer screening (Figure 1) and analyzed with SmlTree. The first strategy (screening mammography) consisted of annual

Note. The analysis compared two strategies for controlling breast cancer: (1) annual screening mammography for all women 50 years of age and older and (2) routine clinical breast examination. Data used for the clinical breast examination strategy reflected incidence of breast cancer, current levels of screening, and breast cancer outcomes in the population. Breast cancer outcomes are shown in the inset and include stage at diagnosis and stage-specific 5-year survival.

FIGURE 1—The decision tree: two strategies for controlling breast cancer.

screening mammography and clinical breast examination in women 50 years of age and older. Consistent with logistic considerations in the IHS, this strategy is based on the use of mobile mammography units with intensive community outreach to encourage use of the screening opportunity. The second strategy (clinical breast examination) reflects current screening practices in most IHS programs, which rely largely on periodic clinical breast examination followed by diagnostic mammography for suspicious masses. Current data for incidence, stage at diagnosis, and stage-specific survival were used to model the second strategy as described below.

The analysis consisted of three components. First, the base analysis compared the two screening strategies for the (1) distribution of stage at diagnosis, (2) specific 5-year relative survival, (3) deaths prevented at 5 years, (4) cost per death prevented, and (5) total costs of breast cancer. In order to put the results of the study into a community perspective, the results of the decision analysis were applied to the age and gender distribution of a specific American Indian community in the southwestern United States. The community used is typical in size and age–sex distribution of many reservation-based communities served by the IHS. It consists of 13 620 people, with 2 888 women 25 years of age and older. The model expressed the effect of the two screening strategies on the 775 women in this population 50 years of age and older.

A second analysis examined the sensitivity of the outcomes applied to the study community to critical assumptions of the analysis, including the cost of mammography, the cost of diagnostic workup of patients with positive screening tests, and patient compliance in obtaining mammograms.

A third analysis examined the effect of the underlying incidence of disease in the population on the outcomes of the decision analysis. This was accomplished by varying the rate of breast cancer in the analysis using incidence figures for American Indian women in Arizona and New Mexico, Alaska Native women, and White women in New Mexico. The results of the analysis for each group were applied to the age and gender distributions of the study community.

Estimates of Incidence, Stage at Diagnosis, and Survival

Estimates of the annual incidence, the stage at diagnosis, and 5-year survival were obtained from the population-based New Mexico Tumor Registry for the years 1973 through 1988. Annual incidence rates for breast cancer for each of four age groups (25 through 39 years, 40 through 49 years, 50 through 64 years, and 65 through 89 years) for Navajo and non-Navajo Indian women in Arizona and New Mexico, White women in New Mexico, and Alaskan Native women were computed and age adjusted to the 1970 US population.

The analysis used estimates of the distribution of stage at diagnosis of breast cancer with and without a screening mammography program developed by the National Cancer Institute Working Group on Cancer Screening and Detection.[11] These estimates were based on the 30% reduction in breast cancer mortality for women 50 to 70 years of age reported in the literature. Criteria established by the American Joint Committee on Cancer[12] were used to compute the observed stage at diagnosis for Navajo and non-Navajo Indian women in Arizona and New Mexico from New Mexico Tumor Registry data.

The Kaplan-Meier product-limit method was used to produce a survival function from the registry data. Cases that were not known to involve death were censored at the date of last documented follow-up. Stage-specific survival rates at 5 years were obtained from the survival function and computed separately for Navajo and for all other Arizona and New Mexico Indians (tables showing the age-specific estimates of incidence, distribution of stage at diagnosis, and stage-specific survival rates at 5 years for Navajo and non-Navajo American Indian women in Arizona and New Mexico used in the analysis are available on request from the authors).

Costs and Assumptions Used in the Analysis

The assumptions incorporated into the analysis that dealt with cost, participation rates, and sensitivity and specificity of the screening and diagnostic procedures are summarized in Table 1. The analysis assumed a 50% response and compliance with annual screening mammography over 5 years, consistent with the rate for all scheduled screenings in the Health Insurance Plan study[13] but lower than the

initial response reported from the Group Health Cooperative of Puget Sound study.[14] The analysis also assumed that those individuals responding to the invitation for screening were of the same risk level and thus had the same distribution of cancer by stage as those not responding. Finally, the analysis assumed that 95% of women would comply with the diagnostic workup that followed positive mammography.[11]

The sensitivity and specificity of screening mammography were assumed to be 75% and 94%, respectively, based on reports from the Canadian National Breast Screening Study.[15] The primary analysis also assumed that the sensitivity and specificity of surgical biopsy were both 100%. The probability of a positive screening test is a function of the prevalence of undetected breast cancers in the population presenting for screening and the sensitivity and specificity of the screening strategy used. The prevalence of undetected cancers was estimated from the annual incidence of breast cancer in the population, with the recognition that this approximation may underestimate prevalence in the initial years of the screening program when prevalent (but previously undiagnosed) cases are found.

The primary analysis assumed a cost of $30 per mammogram including interpretation, a rate that was under negotiation for another study within the IHS. Reported estimates range from $20 to $200,[16-19] and sensitivity analysis examined the impact of varying this estimate from $20 to $120. The cost of clinical breast examination has been estimated from $10 to $50[18] and as low as $3.25 when conducted during a regular examination rather than during a separate visit.[17] For the primary analysis, it was assumed that women receiving screening mammography would receive a clinical breast examination at the same time, at a cost of $3.25. The primary analysis also included a cost of outreach of $25 per patient participating in the mammography screening program. This was estimated to be the per-patient cost associated with the community health worker time required to publicize the program and the common practice of providing transportation for many patients to the health care facility. Estimates of biopsy costs vary widely, ranging from $500[20] to nearly $2000.[21] A study in the Alaska area of IHS estimated the cost of biopsy at $100 to $500.[22] For simplicity, the analysis assumed an average cost of $500 to include surgical biopsy and other diagnostic procedures such as additional mammographic views, needle aspiration, or ultrasound examinations that may be ordered. Sensitivity analysis examined the effect of varying this estimate from $500 to $1500. Estimates of the cost of care for breast cancer by stage of the disease and for terminal care were modified from those of Eddy,[18] which were based on Medicare data.

TABLE 1—Assumptions Used in the Primary Analysis

Screening mammography with breast self-examination	
Sensitivity	0.75
Specificity	0.94
Response for annual screening, %	
Mammography	50
Compliance with referral for breast examination	95
Compliance with referral for diagnostic mammography	95
Cost of screening and diagnosis, $	
Mammography	30.00
Biopsy	500.00
Cost of outreach	25.00
Cost of clinical breast exam (done at time of mammography)	3.25
Cost of care for cancer patients, $	
Stage 0	7 970
Stage 1	8 219
Stage 2	8 809
Stage 3	8 809
Stage 4	11 859
Terminal care	24 500

Results

Comparison of Outcomes

The "screening breast examination" arm of the decision tree examined the baseline cancer deaths and costs of care for breast cancer patients in the absence of a program of screening mammography. Table 2 shows these data for a 5-year period applied to several age categories of the study community. The results show relatively few breast cancer deaths (1.85) over a 5-year time frame in women 25 years of age and older; 34% of these occur in the age group 25 through 49, which, despite recommendations for women 40 to 49 years old, is generally not considered a target population for regular screening mammography.

In comparison, the "screening mammography" arm of the tree modeled the effect of an intervention that offered annual screening mammography and clinical breast examinations for all women 50 years of age and older. Table 3 summarizes the costs and effects of the mammography strategy when applied to the age distribution of the study community. Offer-

TABLE 3—5-Year Cumulative Costs and Effects of Mammography Screening for Breast Cancer in Women 50 Years of Age and Older in the Study Community

Cancer deaths expected	1.22
Cancer deaths experienced	0.88
Cancer deaths prevented	0.34
Reduction in deaths, %	27.9
Cost of screening mammography program, $	32 002
Cost of care for cancer patients, $	9 617
Total cost, $	41 619
Screening program cost per cancer death prevented, $	94 124

Note. Screening involves annual screening mammography of all women 50 years of age and older. n = 1059.

TABLE 4—5-Year Cumulative Costs and Outcomes of Screening in a Single Study Population Based on Assumptions of Baseline Incidence Rates as Observed in Different Populations

	Non-Navajo American Indians in Southwest 40–49 Years Old	Non-Navajo American Indians in Southwest 50 Years of Age and Older	Alaska Natives 50 Years of Age and Older	Whites in New Mexico 50 Years of Age and Older
No screening program				
Age-adjusted incidence (per 100 000)	27.1	56.5	116.6	294.5
Deaths expected with no screening program	0.59	1.22	2.49	6.27

Screening program				
Deaths prevented	0.14	0.34	0.68	1.72
Expected cost of care for cancer patients, $	4 829	9 617	19 804	50 039
Cost of screening program, $	32 002	32 002	32 002	32 002
Total cost, $	36 831	41 619	51 806	82 041
Cost of screening program per death prevented, $	228 585	94 124	47 062	18 606

Note. Incidence rates were age adjusted on 5-year intervals to the study population.

ing annual screening mammography to women 50 years old and older in this community over 5 years increases the cost of breast cancer care by a factor of 3.6 (from $11 477 in the baseline for cost of care of cancer cases to $41 619 for total program cost with the screening program). The cost is associated with a 27.9% decrease in cancer deaths (from 1.22 to 0.88) over the same 5 years. There is also a small savings in cost of care with screening: a decrease from $11 477 to $9 617, clearly not enough to offset the higher cost of the screening program itself. In comparison with the baseline, the cost of the screening mammography program is $94 124 for each cancer death averted over 5 years of program operation.

Sensitivity Analysis

Sensitivity analysis was conducted to examine the effect of the cost estimates for mammography used in the primary analysis. The findings suggest that the decision result is not very sensitive to the cost of mammography: a fivefold increase in cost of mammography (from $20 to $100) increases the cost per death prevented by only 10.1%.

Sensitivity analysis was also conducted for the cost of surgical biopsy and other diagnostic procedures, examining the effect of varying the cost from $500 (as used in the base analysis) to $1500, which increased the overall program cost by less than 10%.

Sensitivity analysis also examined the effect of varying the assumption of 50% compliance with screening mammography from 10% to 90% on the total cost, cancer deaths prevented, and cost per cancer death prevented. The total program cost over 5 years in the study community increases steadily (from $6400 to $58 354) with the response rate, consistent with the observation that the majority of the cost is associated with the screening and diagnostic procedures, with reductions in the cost of care for late stage and terminal cases being small in comparison. Assuming that the individuals at highest risk are neither the early nor the late responders, the number of deaths prevented decreases steadily with decreasing response rates. For example, at a 90% response rate, approximately 50% of baseline cancer deaths could be prevented in the age group 50 years and older. At a response rate of 67%, approximately 30% of baseline deaths would be prevented, consistent with the observations of most large-scale studies of screening mammography.

The effect of varying the compliance rate with screening on the rate of early detection of breast cancer was also examined; stage 0 or 1 at diagnosis was considered early detection.[17] Across the full range of response rates, annual screening mammography produces early detection rates from 18.4% to 58%.

Effect of Varying Incidence Rates

The decision to make screening mammography services widely available through the IHS is confounded by the varying incidence rates of breast cancer among different American Indian and Alaska Native communities. The effect on program outcome of different incidence rates of breast cancer was examined. The age-specific incidence rates for American Indians in Arizona and New Mexico, Alaska Natives, and White women in New Mexico were age adjusted on 5-year intervals to the study population to compute an age-adjusted incidence for women in each group 50 years of age and older and for American Indian women in Arizona and New Mexico 40 to 49 years old. The different incidence rates were then used in the model and applied to the study population. Table 4 compares program cost and outcome for the different

incidence rates. These data suggest that the cost per death prevented by screening decreases with increasing breast cancer incidence, while the benefit in terms of deaths prevented increases rather sharply even though screening produces a constant reduction in deaths of 20% to 30% at all incidence levels. Figure 2 shows the cost per cancer death prevented at different incidence rates. Clearly, the cost per death prevented not only is higher at the comparatively lower incidence rates common among American Indian communities but rises very steeply for low incidence rates. At the incidence observed in 40- to 49-year-old Indian women in the Southwest, the cost per death prevented by screening is 12 times higher than the cost at an incidence rate common in White women 50 years old and older.

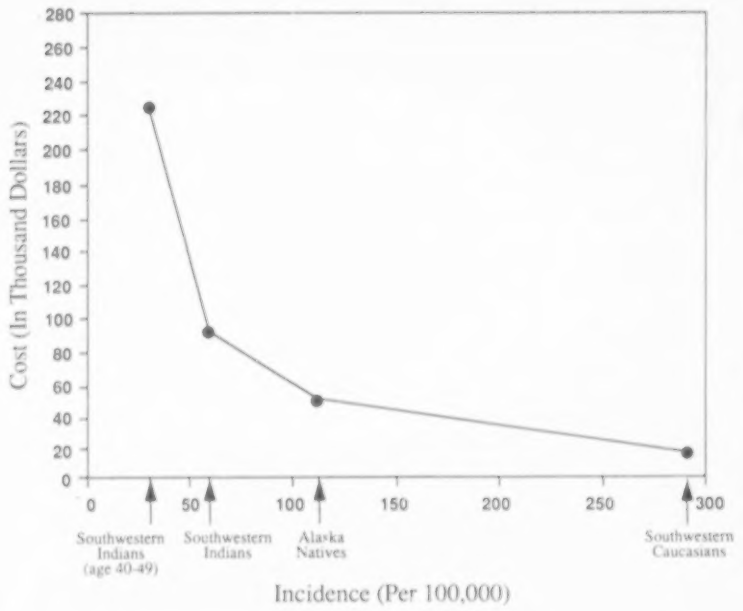

FIGURE 2—Cost per death prevented over 5 years as a function of baseline incidence of breast cancer in women 50 years of age and older.

Discussion

The primary analysis suggests that annual screening mammography could be expected to result in a 27.9% reduction in breast cancer deaths over 5 years. Applying the model output to a specific reservation-based Indian community with a low incidence of breast cancer and a youthful age distribution helps put program outcomes in perspective. For example, the baseline mortality reduction is small in absolute terms, since in the study population of 13 620 only 1.22 breast cancer deaths in women 50 years of age and older would be expected over 5 years in the absence of a screening program. Of these, 34% of deaths are expected in the age group under 50 years, a group that might not be targeted in a screening mammography program. Seen another way, offering screening mammography to this community would save a breast cancer life once in every 15 years at a program cost of $124 857 over the same period.

Since there are relatively few instances of breast cancer, the cost of care for cancer patients is relatively small in comparison with the cost of the screening program in many American Indian communities. The cost of cancer patient care projected for the study population over a 5-year time frame decreased by 16.2%, from $11 477 at baseline to $9617 with mammography. Although the cost of screening will not be substantially offset by reductions in the cost of care for patients with breast cancer in American Indian and Alaska Native communities, cost of cancer care exceeds cost of screening when dealing with the incidence levels of White women of the Southwest (Table 4).

Estimates of the cost-effectiveness of screening mammography have varied widely,[16,18,21,23-25] from a high of $126 000[18] to a low of $5600[25] per year of life saved when compared in 1991 dollars.[23] Our primary outcome measure, cost per cancer death prevented in the study community over 5 years of annual screening, is not easily translated to cost per year of life saved. When we apply our model to the cancer incidence observed in White women in the Southwest, however, we conclude that terminal care costs exceed the cost of the screening program and that the program costs $18 606 per death prevented. Both suggest more screening benefit than shown in previous studies. It should be noted that applying White incidence rates to our model does not constitute an analysis of program effect in a White community. All other assumptions specific to the American Indian and Alaska Native populations are retained, including a relatively late stage at diagnosis (in the absence of screening) and relatively poor stage-specific survival, both of which will magnify the benefit of screening mammography.

This study demonstrates the danger of applying a uniform clinical policy across populations with differing baseline disease rates, stage at diagnosis, and stage-specific survival. The analysis suggests that several program outcomes are sensitive to the changing incidence of breast cancer in women 50 years old and older, as might be seen across different ethnic populations or across international borders. Under base assumptions with results applied to the study community, the cost of the screening program per breast cancer death prevented rises sharply from $18 606 when using incidence rates observed in southwestern White women to $94 124 for rates from southwestern Indian women. Moreover, the cost per death prevented increases even further to $228 585 for the incidence rates observed among southwestern Indian women between the ages of 40 and 49 years.

The finding that cost and program outcome are related to baseline incidence in the population is consistent with fundamental principles of epidemiology. That the trends are as striking in the range of incidence rates observed in American Indian women, however, is of considerable policy importance. It underscores the point that a relatively greater impact can be achieved by addressing health problems that are relatively common rather than those that are rare. It also empha-

sizes the importance of targeting high-risk groups, particularly in populations with low baseline incidence, and thus increasing the prevalence of breast cancer in the group to be targeted with screening.

An adverse distribution of stage at diagnosis and poor stage-specific survival have been observed among many ethnic minorities.[10,26–28] As might be expected, the impact of screening mammography appears to increase in populations with worse distributions of stage at diagnosis, such as the Navajo population. When Navajo women were compared with other Indian women, the analysis suggested a further 26.4% reduction in 5-year mortality and a reduction in cost per death prevented from $94 124 to $78 054. These effects assume no change in stage-specific survival. The poor stage-specific survival, however, emphasizes the importance of considering other intervention strategies for breast cancer mortality reduction as well. For example, a simple analysis based on the stage-specific survival data used in the model suggests that important reductions in deaths at 5 years might be achieved (in the absence of screening mammography) by improving stage-specific survival to the level of other American Indian communities in Arizona and New Mexico (a 24.1% reduction) or to the level observed in Surveillance Epidemiology and End Result programs[29] for all races (a 42.4% reduction). The reduction possible by raising the survival to the level of other Indian communities is nearly the same as that achievable by screening mammography and deserves further study.

Conclusions

This study developed a decision model to examine the cost and outcomes associated with screening mammography in American Indian communities. Results suggest that cost per death prevented is very sensitive to baseline incidence and that the relationship is much less favorable in the range of incidence common in American Indian communities. The analysis also examined the relative impact of improving stage at diagnosis through improved screening compared with the impact of improving stage-specific survival through case management strategies. When applied to a population with an adverse distribution of both stage at diagnosis and stage-specific survival, the results suggest that important reductions in preventable deaths might be achieved through combinations of screening and case management. The results illustrate the potential effects of multiple intervention strategies and highlight the danger of applying a uniform clinical policy across populations with differing disease characteristics. □

HIV Infection among Women in Prison: An Assessment of Risk Factors Using a Nonnominal Methodology

Catherine A. Hankins, MD, MSc, Sylvie Gendron, MSc, Margaret A. Handley, MPH, Christiane Richard, MD, Marie Thérèse Lai Tung, and Michael O'Shaughnessy, PhD

ABSTRACT

The relative contributions of needle use practices and sexual behaviors to human immunodeficiency virus (HIV) antibody seropositivity among 394 women incarcerated in Quebec were determined by risk factor assessment and serology with a nonnominal methodology. HIV positivity was found in 6.9% (95% confidence interval [CI] = 4.6, 9.9) of all participants and in 13% (95% CI = 8.6, 18.6) of women with a history of injection drug use. HIV seropositivity among women with a history of injection drug use was predicted by sexual or needle contact with a seropositive person, self-reported genital herpes, and having had a regular sexual partner who injected drugs, but it was not predicted by prostitution. Nonnominal testing is an ethical alternative to mandatory and anonymous unlinked testing among correctional populations. (*Am J Public Health.* 1994;84: 1637–1640)

Introduction

Individuals entering correctional institutions may have been at risk for acquiring human immunodeficiency virus (HIV) infection through injection drug use practices or unprotected sexual activity.[1,2] Among women inmates, prior injection drug use has been associated with HIV infection,[3] and those under age 25 appear more likely to be infected than similarly aged incarcerated men.[4]

Studies that detail previous risk behaviors can inform the design of interventions to reduce HIV transmission both in prisons and in the outside community. The objective of the first such study in Canada was to examine, with a nonnominal methodology, the relative contributions of preincarceration needle use and sexual practices to HIV antibody seropositivity among incarcerated women.

Methods

Study participation was inmate initiated and confidential. Freely given informed consent was obtained before private administration of a risk factor questionnaire and venipuncture. A numbered ticket chosen randomly from a box by the inmate allowed for the nonnominal linkage of questionnaire data to serological results. Pretest counseling followed to assist the inmate in determining whether she wished to learn her serostatus. On subsequent presentation of her number (while incarcerated, on release, or thereafter), a consenting inmate was informed of her results. No information was provided to the prison health service or administration. After posttest counseling, medical and psychosocial referrals were arranged on request.

Serological determinations for HIV antibodies were done with commercial enzyme-linked immunoassays, immunoblot, and/or radio immune precipitation assay following World Health Organization criteria.[5] Basic sociodemographic data were compiled on all admissions during 1988 and 1989 for prison stays of 1 week or longer.[6] Chi-square tests, Student's *t* tests, Fisher's exact tests, and forward stepwise logistic regression were used to examine the relationship between HIV seropositivity and risk factor data. Mantel–Haenszel estimators for odds ratios and Miettinen's test-based 95% confidence intervals (CIs) are reported.

Results

A total of 394 women participated, with Montréal residents ($P < .001$) and women of Black and other (nonaboriginal) origin ($P < .001$) overrepresented in the study (Table 1). Participants also had lower educational levels than those of the general prison population ($P < .001$).

Overall, 6.9% of participants, 13.0% of women with a history of injection drug use, and 12.9% of those for whom

prostitution had been the principal source of revenue before incarceration were seropositive for HIV antibodies (Table 2). Tables 3 and 4 present selected results of bivariate analyses. In light of the preponderance of injection drug use among seropositive women (25/27), further analysis was restricted to the 192 women who had injected drugs (Table 5).

In forward stepwise logistic regression, the variables "subject awareness of previous sexual or needle contact with a person with HIV infection" (adjusted odds ratio = 6.5, 95% CI = 2.6, 16.5; $P < .001$), "self-reported genital herpes" (adjusted odds ratio = 5.5, 95% CI = 1.5, 20.1; $P = .01$), and "having had a regular sexual partner since 1979 who ever injected drugs" (adjusted odds ratio = 2.7, 95% CI = 1.0, 7.6; $P < .05$) were found to be significantly associated with the probability of HIV-1 infection. Although the confidence interval for the last variable includes the value of 1, reducing the statistical certainty that its addition improves the existing model, a log likelihood ratio test comparing this last model with one including only the first two variables was significant. After including these three variables in the model, the factors "prostitution in the year pre-incarceration" and "number of years injecting" were not significantly associated with HIV infection.

Discussion

Few studies have examined the risk behaviors of incarcerated women.[3,7–9] This study indicates that injection drug use is the predominant risk factor for HIV infection among women inmates and that needle use practices contribute substantially to the risk of HIV infection among injection drug users. The significant contribution of self-reported *Herpes simplex* infection in logistic modeling supports the hypothesis that mucosal disruption increases susceptibility to viral acquisition[10] and emphasizes the importance of sexual risk factors. The selective contribution of the latter was difficult to differentiate because both needle sharing and unprotected sexual activity are likely to have occurred with at-risk partners.

Self-selection bias[9,11,12] may have led to an underestimation or overestimation of true HIV prevalence in this correctional institution. However, because the prevalence of reported risk behaviors was high and the sample size was large, participation bias is unlikely to have greatly affected HIV-associated risk be-

havior findings. Differential recall may have occurred for the time period under study, depending on the proximity of participation dates to prison entry.

Freely given consent with no penalties for participation or refusal is considered the most ethical approach to the study of HIV infection in correctional settings because it permits inmates to weigh the risks and benefits of participation.[13–15] The further step of isolating consent for research participation from pretest counseling procedures in this study allowed participants to freely decide whether or not to return for their serological results. The anonymity provided by voluntary nonnominal participation gave seropositive study subjects additional control of subsequent decisions to initiate medical and psychosocial follow-up. The nonnominal methodology employed in this study has research utility, permitting linkage of serological information to risk factor and demographic data, whether the latter is collected at prison entry, from inmate medical charts before testing, or through standardized interviews, as was done here.

Some studies comparing seroprevalence among prison entrants tested blindly with that among prison entrants volunteering under nonnominal or anonymous conditions have found no differences.[11,16] The introduction of voluntary testing can thus lead to increases in HIV detection, resulting in earlier initiation of prophylaxis and treatment.[17] Because some elements of disincentive are likely present in nominal testing even when confidentiality is ensured,[12] anonymous or nonnominal testing options can increase the effectiveness of voluntary testing in identifying inmates with HIV infection. In contrast to anonymous testing, which by definition must be provided by an outside team unaware of the identity of participants, nonnominal testing can be offered by correctional health services.

The correctional setting can be an important site for monitoring community drug use behavior, given the excellent availability of study volunteers with fewer time constraints. More injection drug users can be found in prisons than in drug treatment programs, hospitals, and social services.[18] In addition, reported preimprisonment behaviors related to drug use can be anticipated to be more heterogeneous among injection drug users studied in prison than among those studied in treatment facilities or at needle exchange programs.[19] Finally, the logistical ease of providing nonnominal voluntary testing combines with inmate compliance to challenge the belief that such testing cannot be provided in a prison setting. HIV-1 testing programs should be expanded to include voluntary, confidential, and anonymous testing, or failing this, nonnominal testing with incorporation of flexible follow-up options for the provision of test results. □

Risk Factors for Acute Non-A, Non-B Hepatitis and Their Relationship to Antibodies for Hepatitis C Virus: A Case–Control Study

Alfonso Mele, MD, Luciano Sagliocca, MD, Giuseppe Manzillo, MD, Francesco Converti, MD, Pietro Amoroso, MD, Maria Antonietta Stazi, MSc, Luigina Ferrigno, Mariella Rapicetta, MD, Elisabetta Franco, MD, Brunella Adamo, MD, Filippo Palumbo, MD, Costanza Sbreglia, MD, Augusto Panà, MD, Paolo Pasquini, MD, and the SEIEVA Collaborating Group

ABSTRACT

A case–control study was carried out comparing 333 case subjects with non-A, non-B hepatitis and 1095 hospital control subjects. Of 333 case subjects, 197 (59%) were positive for hepatitis C antibody (anti-HCV). Excluding blood transfusion and intravenous drug use, surgical intervention and dental therapy were strongly associated with anti-HCV–positive cases: in particular, obstetric and gynecology surgical intervention was found to be strongly associated with HCV positivity (odds ratio [OR] = 32; 95% confidence interval [CI] = 7, 147). Raw shellfish consumption was a risk factor for anti-HCV–negative cases (OR = 2.2; 95% CI = 1.0, 5.1), thus suggesting an enterically transmitted virus in sporadic non-A, non-B hepatitis in Italy. (*Am J Public Health.* 1994;84:1640–1643)

Introduction

Non-A, non-B hepatitis includes several agents that are both blood and enterically transmitted.[1–3] A large number of patients with blood-transmitted non-A, non-B hepatitis may develop chronic liver disease. Blood transfusions and intravenous drug use explain fewer than 50% of the hepatitis cases; therefore, identification of additional risk factors for the disease is necessary.[4,5]

Risk factors associated with non-A, non-B hepatitis were evaluated in a case–control study based in three Naples hospitals (Italy) from November 1987 through May 1991.

Study Population and Methods

All case subjects were recruited in an infectious-diseases hospital, had serum

aminotransferase levels at least three times greater than the upper limit of normal values, and were negative for immunoglobulin M (IgM) antibodies to hepatitis A virus and hepatitis B core antigen (radioimmunoassay method, Abbott Laboratories). No case subject had a history or clinical sign of hepatic injury due to medication, alcohol, or other hepatobiliar diseases, and case subjects had an onset of disease not longer than 2 weeks.

Non-A, non-B case subjects with IgM antibodies against cytomegalovirus (Abbott CMV-M enzyme immunoassay) or with IgM antibodies against Epstein–Barr virus (Ortho monolert) were excluded from the study.

Serum samples from all case subjects were stored at −80°C.

Assays for hepatitis C antibodies (anti-HCV) were done before 1990 with the first-generation enzyme-linked immunosorbent assay (ELISA) (Ortho Diagnostics). Thereafter, the second-generation test was applied to all new cases and to serum samples that were negative for anti-HCV by the first-generation ELISA. Serum samples that showed an optical density between 0.7 and 1.7 were retested by supplemental second-generation recombinant immunoblot assay (RIBA) and were considered positive when two or more bands were present.

All anti-HCV–negative case subjects recruited from 1990 were followed-up for at least 6 months (range, 6–15 months).

The following control subjects were chosen: (1) patients without bloodborne and enterically transmitted disease admitted to the same hospital as the case subjects; (2) patients from the neurosurgery and ear, nose, and throat wards of a pediatric hospital; and (3) patients from the emergency, orthopedics, and surgery wards of a general hospital. Both the pediatric and general hospitals were located in the same area as the infectious-diseases hospital.

Case and control subjects lived in the same area and were interviewed on admission to the hospitals. Data for children were obtained from the mothers.

Exposure within 6 months and 6 weeks of the onset of disease was investigated for parenteral risk factors (including sexual exposure) and raw shellfish consumption, respectively, by means of a standardized questionnaire.

Age groups used for analysis were 0–9, 10–14, 15–19, 20–34, 35–54, and ≥ 55 years.

TABLE 1—General Characteristics of Control and Case Subjects, Naples, Italy, 1987 through 1991

	Subjects, %		
		Case	
Age, y	Control (n = 1095)	Positive for Hepatitis C Virus Antibody (n = 197)	Negative for Hepatitis C Virus Antibody (n = 136)
0–9	18.9	1.0	13.2
10–14	8.8	0.5	12.5
15–19	13.6	14.2	19.1
20–34	20.2	64.5	39.0
35–54	20.8	11.7	14.0
55 and over	17.7	8.1	2.2

TABLE 2—Diagnoses of Control Subjects (n = 1095)

Diagnosis	Percentage
Infectious diseases (Measles, mumps, brucellosis, rickettzial diseases, respiratory tract infections, encephalitis, herpes zoster, varicella, mononucleosis, toxoplasmosis)	13.3
Diseases following trauma and emergency surgery (Fractures, dislocations, abdominal trauma, acute appendicitis, cranial trauma)	22.9
Diseases undergoing surgical treatment (Orthopedic surgery, anorectal diseases, thyroid diseases, breast benign diseases, inguinal hernia)	32.1
Ear, nose, and throat diseases	9.7
Others (Inflammatory gastrointestinal diseases, depression, or arterial peripheral diseases, respiratory diseases, renal colic, irritable bowel syndrome)	21.9

Note. Two hundred twenty-one patients were recruited in the infectious-diseases hospital.

The polychotomous logistic technique was used to estimate the independent effect of the studied exposure variables on the risk of being either anti-HCV positive or anti-HCV negative.[6,7]

We first considered intravenous drug exposure, blood transfusion before and after 1990, age, sex, and education and thereafter the effects of all other exposure variables.

First-order interaction terms were always tested.

Results

Three hundred and forty-two case subjects and 1095 control subjects were recruited. Of the 342 case subjects, 251 (73%) were jaundiced; serum samples were taken from all case subjects within 21 days of the onset of disease. Four case subjects positive for IgM antibodies against cytomegalovirus and five positive for IgM antibodies against Epstein–Barr virus were excluded.

Of 333 case subjects, 187 (56%) were anti-HCV positive by the first- or second-generation test at first blood drawn (70 of 148 negative samples at first-generation ELISA were positive at second-generation ELISA and two of eight serum samples with an optical density between 0.7 and 1.7 were confirmed by second-generation RIBA).

Among the 68 anti-HCV–negative subjects followed-up, 10 (15%) became anti-HCV positive (second-generation test, second-generation RIBA confirmed): 5 subjects after 45 days from the onset of disease, 3 subjects after 2 months, and 2 subjects after 4 months. Overall, 164 of 248 (66%) males and 33 of 85 (39%) females were anti-HCV positive.

TABLE 3—Case and Control Subjects Exposed to Intravenous Drug Use and Blood Transfusion, Naples, Italy, 1987 through 1991

	Control Subjects		Case Subjects					
			Anti-HCV Positive			Anti-HCV Negative		
Risk Factor	%	Total No.[a]	%	Total No.[a]	OR (95% CI)	%	Total No.[a]	OR (95% CI)
Intravenous drug use	0.7	1086	51.3	195	71.0 (32.0, 160.0)	13.3	135	13.0 (5.3, 31.0)
Blood transfusion (1987–1989)	0.8	759	14.8	128	49.0 (17.0, 140.0)	4.6	87	7.0 (1.9, 27.0)
Blood transfusion (1990–1991)	0.3	333	1.4	69	1.9 (0.01, 270.0)	0.0	48	Not calculable

Note. Adjusted ORs (95% CIs) were estimated by polychotomous logistic regression according to positivity for hepatitis C virus antibody (anti-HCV). ORs were adjusted for age, sex, education level, and the other listed variables.

Hospitalization	10.3	1079	22.8	79	0.8 (0.3, 2.0)	17.5	114	1.1 (0.6, 2.3)
Dental therapy	11.0	1079	22.4	76	1.9 (1.0, 3.5)	13.2	114	1.2 (0.6, 2.1)
Other percutaneous exposures[b]	2.1	1072	5.1	78	1.7 (0.5, 6.0)	5.4	111	1.8 (0.7, 4.8)
More than one sexual partner[c]	6.6	775	16.9	77	1.4 (0.7, 3.0)	11.5	78	1.2 (0.5, 2.7)
Raw shellfish	5.7	715	16.7	54	1.4 (0.6, 3.6)	13.6	66	2.2 (1.0, 5.1)

Note. Adjusted ORs (95% CIs) were estimated by polychotomous logistic regression according to positivity for hepatitis C virus antibody (anti-HCV). ORs were adjusted for age, sex, education level, and the other listed variables.
[a]Discrepancies in the numbers are due to missing values ("I don't know" answer).
[b]Ear piercing, tattooing, acupuncture, electrolysis, or attendance at a chiropodist or manicurist.
[c]Age greater than 14 years.

In Tables 1 and 2 general characteristics of case and control subjects are presented: 26% of the anti-HCV–negative case subjects vs 1.5% of the anti-HCV–positive ones were younger than 15 years.

Among the case subjects, 118 were intravenous drug users and 24 received blood transfusions. The odds ratios were much higher for both these risk factors among anti-HCV–positive case subjects than among anti-HCV–negative ones (Table 3).

Of 215 case subjects, 23 (11%) reported receiving blood transfusions from 1987 through 1989; 1 of 117 case subjects (0.9%) received a blood transfusion after 1989.

Two anti-HCV–positive case subjects who were intravenous drug users received blood transfusions, 3 had surgery, and 43 had multiple sexual partners. Of the 20 anti-HCV–positive case subjects who received blood transfusions, 15 also had surgery.

After excluding blood transfusion and drug use, surgical intervention was significantly associated in both case series, and the risk was higher in anti-HCV–positive case subjects than in the anti-HCV–negative ones (Table 4). The strongest association was found in female case subjects age 15–44 years for obstetric and gynecology interventions: odds ratio (OR) = 32.0 (95% confidence interval [CI] = 7.5, 147.0) for anti-HCV–positive cases; OR = 16.5 (95% CI = 4.0, 73.0) for anti-HCV–negative cases. When control subjects undergoing surgical treatment were excluded, the ORs were 18 (95% CI = 5.1, 66.0) among anti-HCV–positive cases and 7.5 (95% CI = 2.6, 22.0) among anti-HCV–negative cases.

Dental therapy was associated with anti-HCV–positive cases, and a nonsignificant association was found between other percutaneous exposures and both cases series. A small but not significant excess of risk (OR = 1.4; 95% CI = 0.7, 3.0) was found among anti-HCV–positive case subjects exposed to multiple heterosexual partners (Table 4).

Thirty-three of 197 (17%) anti-HCV–positive case subjects and 66 of 136 (49%) anti-HCV–negative case subjects did not report any considered parenteral exposure.

A significant association existed between raw shellfish consumption and anti-HCV–negative cases. Raw shellfish consumption was the only risk factor for 7 of 66 (11%) anti-HCV–negative case subjects vs 3 of 54 (6%) anti-HCV–positive case subjects (Table 4).

No effect modification was found between the considered risk factors.

Discussion

More than 50% of the case subjects with non-A, non-B hepatitis were anti-HCV positive, but the diagnosis of acute hepatitis C is reliable only for the 10 case

subjects of 68 (15%) who seroconverted during the follow-up.

Blood transfusion and intravenous drug use account for 61% of the anti-HCV–positive cases and 16% of the anti-HCV–negative cases. Surgical intervention, dental therapy, and other percutaneous exposures are additional parenteral risk factors found to be associated with non-A, non-B hepatitis. Interestingly, the strongest association was shown with obstetric and gynecological interventions. Given that a large proportion of the general population is exposed to these risk factors, the present results and those reported for hepatitis B[8] underscore the importance of implementing efficient procedures for sterilization of instruments and the use of disposable materials, especially when a high turnover of patients combined with emergency surgical intervention (such as in gynecology) represents an increased risk of infection.

Few case subjects with non-A, non-B hepatitis and a history of blood transfusion were enrolled after 1989, when the anti-HCV test was introduced in the screening of blood banks. That fact suggests that a high number of non-A, non-B cases of hepatitis in patients reporting a history of blood transfusion were due to hepatitis C virus.

Heterosexual transmission of hepatitis B, non-A, non-B, and C viruses has been outlined in previous studies.[9–11] Our data show a slight (OR = 1.4; 95% CI = 0.7, 3.0) but not significant excess of risk for anti-HCV–positive case subjects exposed to multiple sexual partners.

The estimated odds ratios for blood transfusions, intravenous drug use, surgical intervention, and dental therapy were higher in the anti-HCV–positive cases. Although the anti-HCV test applied in this study does not discriminate acute from past infection, anti-HCV positivity elicits a group of non-A, non-B case subjects older than the anti-HCV–negative case subjects, and with greater exposure to parenteral risk factors. At present no test for additional non-A, non-B parenteral viruses is available, but it is likely that the anti-HCV–positive group includes acute non-A, non-B cases due to other blood-transmitted and orofecally transmitted viruses. At the same time, the anti-HCV–negative group might include hepatitis C cases.

The association of raw shellfish consumption with anti-HCV–negative cases suggests the possible presence of enterically transmitted non-A, non-B hepatitis in Italy.

Case subjects did not include all the patients with non-A, non-B hepatitis notified in the area, and hospital control subjects were selected in an attempt to avoid the selection process culminating with cases being diagnosed in the study hospital. The pediatric and general hospitals were located in the same area as the infectious-diseases hospital, where the control subjects would have been admitted had they been hospitalized with acute hepatitis. Furthermore, the broad diagnostic representation of control subjects probably prevented control selection bias.

The inclusion of patients undergoing surgical intervention as control subjects might have led to an underestimation of odds ratios: the associations between cases and surgical intervention were stronger after omitting these control subjects.

Control subjects with infectious diseases such as mononucleosis (n = 5) can share some risk factors with case subjects. When these control subjects were excluded, the estimate of odds ratios remained unchanged. □

CDC's Consensus Set of Health Status Indicators: Monitoring and Prioritization by State Health Departments

Sharon L. Zucconi, PhD, and Catherine A. Carson, PhD

ABSTRACT

A survey assessed the extent to which state health departments monitor and prioritize the Centers for Disease Control and Prevention's consensus set of health status indicators. A response rate of 100% was obtained. Although mortality indicators are often monitored, only 75.5% of the states monitor work-related injury deaths. Most states monitor the incidence of acquired immunodeficiency syndrome, measles, tuberculosis, and syphilis. Low birthweight, births to adolescents, and lack of prenatal care are monitored in nearly all states and are considered high-priority problems. Only 46.9% of states are monitoring poor air quality, and only 58.8% are monitoring childhood poverty. Survey results suggest a need for standardized assessment of indicators for policy development and program planning. (*Am J Public Health.* 1994;84:1644–1646)

Introduction

In July 1991, a consensus set of 18 health status indicators was released by the Centers for Disease Control and Prevention (CDC) to assist communities in assessing their general health status.[1] These indicators addressed the requirements of the Year 2000 Objectives Planning Act[2] and objective 22.1 of *Healthy People 2000*.[3]

Priority in selecting the indicators was given to measures for which data are readily available and measures that are commonly used in public health.[1] It is not known, however, whether these indicators are actually being monitored within each state. Therefore, we conducted a survey to determine how the CDC's consensus set of health status indicators (henceforth referred to as "consensus indicators") is being assessed in the United States.

Methods

A four-page survey was mailed to directors of state health departments, as well as the District of Columbia health department, to elicit information about efforts in monitoring CDC's consensus indicators. Questions were also asked about prioritization of health problems and the sources and availability of data to monitor the indicators.

Results

An initial mailing in summer 1992, followed by two mailings to nonresponders, resulted in a cumulative response rate of 100%. As shown in Table 1, most of the consensus indicators are being monitored in all states. In general, mortality indicators are often monitored. However, only 75.5% of the states monitor work-related injury deaths. Most state health departments monitor indicators of acquired immunodeficiency syndrome (AIDS), measles, tuberculosis, and syphilis incidence, which are diseases reportable to the CDC. The incidence of low birthweight, births to adolescents, and the lack of prenatal care are being monitored in nearly all states, and these areas are considered high priorities. However, only 46.9% and 58.8% of states, respectively, are monitoring poor air quality and childhood poverty.

The most common source of mortality data was vital statistics. Two exceptions were (1) Fatal Accident Reporting System data and police reports for monitoring deaths from motor vehicle crashes and (2) worker's compensation data for occupational injuries.

Provision of mortality and incidence data to local health departments was reported by all states with local departments. However, risk factor data were often not available at the county or community level.

Discussion

This paper clearly demonstrates the widespread use of CDC's consensus set of 18 health status indicators by state health departments. However, it also highlights problems in data collection, maintenance, and resource allocation to effectively monitor these indicators.

The consensus indicators were identified, in part, because it was believed that data were readily available at national, state, and local levels.[1] The results of this survey indicate, however, that data for some indicators may actually *not* be readily available. And the availability of

At the time of the study, the authors were with the Health Policy Institute, Graduate School of Public Health, University of Pittsburgh, Pittsburgh, Pa. Sharon L. Zucconi is now with the Nemours Children's Clinic, Health Services Research Center, Jacksonville, Fla. Catherine A. This paper was accepted February 1, 1994.

data had a major influence on (1) whether or not states placed a high priority on the need to monitor and (2) subsequent monitoring of indicators. States were less likely to monitor an indicator if data were unavailable, perceived of lesser quality, or of lower priority.

Sources of information used to monitor each objective may vary for some indicators (i.e., motor vehicle crash deaths, work-related injury deaths). The use of different data sources introduces the possibility of poor reproducibility of rates; differences in rates across communities may be due to different sources of data rather than actual discrepancies in events.

Differences in monitoring may be artifactual (i.e., events may be recorded but not considered indicators unless health departments actually use the information for program planning and/or resource allocation). For example, all states have *access* to mortality data, but these data may not be used for health status indicators. The disparity between data collection and use of data for program planning and evaluation is probably even greater at the local health department level. In the Institute of Medicine's view, assessment is a core function of public health.[4] Hence, the rapid falloff of monitoring beyond the vital statistics indicators and the mixed priority for even those more readily accessible data suggest areas for further research.

States were often not monitoring two consensus indicators: childhood poverty and the proportion of persons living in counties exceeding Environmental Protection Agency standards for air quality (poor air quality). One of the reasons for not monitoring poor air quality may be a lack of available data for counties (i.e., not all counties have air quality stations). It was frequently mentioned that census data are available indicating the number of children less than 18 years of age living in poverty. However, the indicator is for children less than 15 years of age living in poverty. A solution to this problem would be to either have current population survey data compiled for children less than 15 years old or change the indicator to the proportion of children less than 18 years old living in families at or below the poverty level.

Objective 22.1 of *Healthy People 2000*[3] states that the value of public health agencies in assessing the health status of the population is "enhanced when comparisons to some benchmarks, such as other similar populations or to national norms, can be made."[3(p554)] The lack of targets for some of the indicators (e.g., all-cause mortality and childhood poverty) may be a deterrent to monitoring. These indicators are not *Healthy People 2000* objectives[3]; therefore, national targets have not been established for them. In addition, several of the indicators, although similar to specific objectives, do not conform exactly (e.g., cardiovascular disease deaths); precise national targets are not available for this group of indicators. Furthermore, although definitions and national data have been recently published[5] for the consensus indicators, technical support from the CDC is needed to assist communities in establishing local targets.

As stated in objective 22.1,[3(p554)] the indicators should include measures needed for areawide health planning and for allocating health resources among programs, areas, or regions. The key to evaluating progress and comparing results across geographic, political, and programmatic lines is comparability of data. CDC's consensus indicators are widely recognized by the states and are, in effect, being monitored rather consistently, except for a few. This is a first step in achieving comparable data methods and is a key, initial step toward what the Institute of Medicine envisioned as a uniform national data set.[4] The status of these efforts should be assessed frequently as funding changes and indicators are revised.

The results of this survey are useful for evaluating the current and future impact of the consensus indicators. They also indicate a need to provide support for assessing these indicators in a standard fashion, so that they can be compared across the nation, and for policy development and program planning. □

TABLE 1—Health Departments' (n = 51) Monitoring and Prioritization of the Centers for Disease Control and Prevention's Consensus Set of Health Status Indicators

Indicator	Health Departments That Monitor, No. (%)	Departments' Priority		
		High, %	Medium, %	Low, %
Race/ethnicity-specific infant mortality[a]	49 (96.1)	81.4	14.0	4.6
Motor vehicle crash death rate[b]	50 (100)	55.8	27.9	16.3
Work-related injury death rate[b]	37 (75.5)	31.0	38.0	31.0
Suicide rate[b]	49 (98.0)	41.8	32.6	25.6
Lung cancer death rate[b]	50 (100)	72.1	25.6	2.3
Breast cancer death rate[b]	50 (100)	79.1	20.9	0
Cardiovascular disease death rate[b]	49 (98.0)	69.8	27.9	2.3
Homicide rate[b]	48 (96.0)	27.9	44.2	27.9
All-cause mortality rate[b]	46 (92.0)	35.9	43.6	20.5
AIDS incidence[c]	51 (100)	86.0	14.0	0
Measles incidence[c]	48 (94.1)	72.1	20.9	7.0
Tuberculosis incidence[c]	51 (100)	69.8	23.2	7.0
Syphilis incidence[c]	50 (98.0)	59.5	21.4	19.1
Incidence of low birthweight[d]	50 (100)	90.9	9.1	0
Births to adolescents[e]	50 (100)	90.9	9.1	0
Prenatal care[f]	48 (96.0)	97.7	2.3	0
Childhood poverty[g]	30 (58.8)	46.1	30.8	23.1
Proportion of persons living in counties exceeding Environmental Protection Agency standards for air quality[h]	23 (46.9)	20.5	35.9	43.6

Note. The denominator for percentages excludes those states with missing responses. The indicators listed are the CDC's.[1]

[a]As measured by the rate (per 1000 live births) of deaths among infants less than 1 year of age.

[b]Death rate per 100 000 population, age adjusted to the 1940 standard population.

[c]Reported incidence per 100 000 population.

[d]As measured by the percentage of the total number of live-born infants weighing less than 2500 g at birth.

[e]Births to adolescents (females aged 10–17 years) as a percentage of total live births.

[f]As measured by the percentage of mothers who delivered live infants who did not receive prenatal care during the first trimester.

[g]As measured by the proportion of children less than 15 years of age living in families at or below the poverty level.

[h]During the previous year.

Medicare-Certified Home Health Services: National and Regional Supply in the 1980s

ABSTRACT

The number of Medicare-certified home health agencies nearly doubled from 1980 to 1990. Using Health Care Financing Administration data, this study documented national and regional patterns of entry and exit by Medicare home health providers from 1980 to 1990. Nationally, agency origination rates accelerated during the early 1980s and then dropped abruptly in the second half of the decade. The proprietary sector, accounting for approximately 42% of agencies in existence during the period of the study, exhibited the greatest volatility. Regional differences are also evident. Both expansion and contraction in Medicare home health services appear to be a response to the incentives of legislation implemented during this period. (*Am J Public Health.* 1994;84:1646–1648)

Cynthia C. Scalzi, PhD, FAAN, Jacqueline S. Zinn, PhD, Michael J. Guilfoyle, and Sondra T. Perdue, DrPH

Introduction

Between 1967 and 1990, Medicare payments for home health care increased from $25 million to an estimated $4 billion, making such care the fastest growing sector of Medicare expenditures.[1–3] Although demand factors are consistent with continuing industry growth, exit from the Medicare market by home health care providers has been more common than entry since 1987.[4] This study documented variations in the national and regional distribution of Medicare-certified home health agencies during the 1980s.

Methods

Using Health Care Financing Administration (HCFA) data, we constructed a database consisting of all Medicare-certified home health agencies in existence from January 1, 1980, through June 30, 1990 (n = 8593). Agencies were grouped into one of four categories assigned by the Medicare program. A proprietary agency is owned and operated for profit by an individual or a business corporation. Government agencies are run by state, county, or city or other local municipalities. Voluntary agencies are governed by community-based boards and financed by earnings and contributions (mainly visiting nurse associations). Nonprofit agency is a residual category consisting of private, nonprofit facilities operated by all other entities. From these data, we calculated (1) the rate of home health agency origination and termination nationally between 1980 and 1990, (2) regional patterns of origination and termination in each of the 10 HCFA designated fiscal intermediary regions, and (3) variation in Medicare home health agency market entry and exit by agency category. Although identified by the city location of the HCFA regional office, each region represents several states. For example, the Boston region covers all of New England.

The origination rate, defined as the annual incidence of newly certified home health agencies, was calculated as the number of newly certified agencies in the current year divided by the number of operating agencies in the prior year. Agencies established before 1980 were included in the denominator, but not the numerator, of the calculation. The termination rate, defined as the annual rate of attrition from the Medicare program, was calculated as the number of home health agencies terminating participation in the current year divided by the peak number

of certified agencies in operation in the current year.

Results

The origination rate for Medicare-certified home health agencies accelerated during the early 1980s and then dropped abruptly during the latter part of the decade (Figure 1). The Medicare program certified only 233 new agencies in 1980. That number peaked at 1213 in 1984 and then declined to 297 in 1988. Medicare termination rates peaked later in the decade than did origination rates. In 1980, 89 agencies lost their Medicare certification; this number increased to 523 in 1987 and dropped to 263 in 1989. Six regions (Atlanta, Chicago, Denver, Kansas City, Philadelphia, and Seattle) exhibit patterns of market entry across time that approximate the national experience. In Dallas and San Francisco, market entry peaked slightly earlier, in 1983, but exhibited the same pattern of decline and leveling through the remainder of the decade. By contrast, the patterns of origination over time in the Boston and New York regions are relatively flat. All regions approximate the national pattern of terminations portrayed in Figure 1, with rates peaking in 1987 or 1988.

Of the 8593 certified agencies in operation at any time from 1980 to mid-1990, 1508 (17.6%) were voluntary, 2007 (23.4%) were governmental, 3620 (42.1%) were proprietary, and 1458 (17.0%) were private nonprofit. Nationally, rates of origination and termination vary by agency category. Of the 1508 voluntary agencies in operation at any time during the decade, 659 (43.9%) originated and 333 (22.1%) terminated. In comparison, 3284 (90.7%) of the 3620 proprietary agencies originated, and 1551 (42.9%) terminated, during the decade. Originations among private nonprofit home health agencies occurred almost as rapidly: 1078 (73.9%) during the decade. Terminations among private nonprofit agencies were less frequent. Of the 1458 existing, 371 (25.5%) terminated during the decade. For the 2007 government agencies, origination and termination rates were essentially the same: 29.4% (591) and 31.7% (637), respectively.

Seven regions had net percentage increases in the number of home health agencies in operation between 1979 and 1990 that exceeded the national average of 99% (Table 1). The vast majority of agencies in all regions in 1979 were classified as either voluntary or governmental (Table 2). As indicated in Table 3, originations by agency type of control showed substantial regional effects. In virtually all regions, the agency category with the greatest market share at the beginning of the decade also accounted for the highest proportion of new entrants during the decade. In seven of the regional markets, the highest proportion of terminations occurred in the proprietary category (Table 3). In every region, with the exception of Kansas City, the control type with the greatest percentage of originations during the decade also experienced the greatest percentage of terminations.

It is clear from the difference in the rates of origination and termination that some regional markets were more volatile than others. For example, 70% of San Francisco region proprietary agencies in existence at any time during the decade terminated Medicare participation (Table 2). Some regions, notably Kansas City and New York, showed very little change in market share by agency type from the beginning to the end of the decade.

Discussion

Industry growth early in the decade may be linked to legislation that deregulated the industry and stimulated privatization. With the passage of the Omnibus Budget Reconciliation Acts of 1980 and 1981, state licensure requirements for

Note. Originations and terminations occurring prior to 1980 are not included.

Medicare certification were gradually eliminated, opening a floodgate for the entry of proprietary agencies in the home care field.[4,5] The Tax Equity and Fiscal Responsibility Act of 1982 introduced prospective payment for hospitals while retaining cost-based retrospective reimbursement for home care, contributing to the proliferation of hospital-sponsored agencies.[1,7] Paradoxically, whereas for-profit agencies aggressively entered markets in virtually all regions, there was also a higher percentage of terminations among such agencies, averaging 43% nationally as compared with 22% for voluntary agencies and 26% for private nonprofit agencies. Lack of policy coordination may well have contributed to these patterns of growth and decline. In 1985 and 1986, fiscal intermediaries took measures that placed more restrictive conditions on eligibility for home health services under Medicare. As a result, increasing numbers of claims were retrospectively denied on the basis of lack of medical necessity or procedural technicalities.[7] Thus, while some federal policies were intended to stimulate private sector growth and competition, the reimbursement policies of Medicare intermediaries may have thwarted that intent, leading to an increasing termination of participation that peaked in 1987. Further research is needed to assess the impact of growth and decline in Medicare home health participation on access in selected markets. □

Gynecologists' Sex, Clinical Beliefs, and Hysterectomy Rates

Nina A. Bickell, MD, MPH, Jo Anne Earp, ScD, Joanne M. Garrett, PhD, and Arthur T. Evans, MD, MPH

ABSTRACT

This study determined how gynecologists' sex, beliefs, appropriateness ratings, and practice characteristics influence hysterectomy rates in North Carolina. Gynecologists who performed hysterectomies at higher rates were further from training, practiced in areas with fewer gynecologists, and had more patients with abnormal bleeding or cancer. Male gynecologists performed 60% more hysterectomies than female gynecologists, but this may have been because they were further from their training. Appropriateness ratings were affected by gynecologists' attitudes toward surgery, recency of training, and practice case mix, and by patients' expressed desire to avoid surgery, but they did not predict hysterectomy rates. To decrease their chances of undergoing hysterectomy, patients should express their preferences and possibly seek the opinion of more recently trained gynecologists. (*Am J Public Health.* 1994;84: 1649–1652)

Introduction

Tremendous variation exists in rates of hysterectomy, the second most common major surgery performed in the United States.[1] Patient demographics and use of health care resources have not explained much of this variation.[2] Some of it is accounted for by physician age and sex, but most has been attributed to physician uncertainty about the appropriate indications for hysterectomy.[2–5] Uncertainty results from limited information about hysterectomy outcomes, physician judgment, and patient preferences for treatment.[3] Unstudied is the relationship between hysterectomy rates and practicing physicians' beliefs about the appropriateness of surgery or the potential impact of patient preferences. Given the increasing number of female gynecologists,[6] patients' preference for female gynecologists,[7] and the wide variation in hysterectomy rates, we surveyed surgically active gynecologists in North Carolina, a state with one of the highest hysterectomy rates, and studied the association between rates and physicians' sex, ratings of hysterectomy's appropriateness, and beliefs about surgery and the uterus.

Methods

Study Population and Data Collection

Surgically active gynecologists who had completed residency training in gynecology and were licensed by the North Carolina Board of Medical Examiners (n = 671) were eligible for the study. A 106-question survey was mailed in 1990 to all 77 female and 154 randomly selected male gynecologists. The survey included questions about attitudes toward surgery and the uterus; practice characteristics; demographics; and clinical scenarios of women presenting with cervical dysplasia (the most common equivocal indication), bleeding fibroids and/or painful fibroids (the most prevalent indication for hysterectomy), and fear of cancer (a common subjective indication).[2] A follow-up survey to assess case mix was mailed to the 140 respondents of the initial survey.

Statistical Analyses

The hysterectomy rate was calculated using the average number of hysterectomies per month, divided by the number of patients seen per month, multiplied by 100. Gynecologists' self-reported hysterectomy rates were correlated with rates from the North Carolina Hospital Discharge Database ($r = .99$) to confirm their validity. Bivariate and multivariable relationships between hysterectomy rate, attitudes and practice characteristics, and physician demographics were assessed. Physician density by county was calculated by dividing the number of gynecologists in the county by the number of women older than age 15 years in that county.

All scenarios asked about the appropriateness of a hysterectomy for a 45-year-old woman, approximately the average age when women undergo that procedure. Appropriateness was measured on a 9-point scale, on which 1 was extremely inappropriate and 9 was extremely appropriate.

The impact of patients' desire to avoid hysterectomy was assessed by having physicians rate each scenario's appropriateness for women who did and did *not* express an aversion to the procedure. *T* tests compared the mean difference in appropriateness scores.

Factor analysis confirmed physicians' attitudes toward (1) the uterus' contribution to sexual function (six items, Cronbach's alpha = .84); (2) the importance of the uterus for sexual identification (four items, Cronbach's alpha = .92); and (3)

the relative efficacy of hysterectomy compared with medical treatment (six items, Cronbach's alpha = .66) (see Appendix).

Case mix was calculated from physicians' reports of the percentage of all patients who had intact uteri and signs or symptoms of abnormal bleeding, pelvic pain, pelvic relaxation, dysplasia, or cancer.

Response Rate

For the initial survey, 190 of 231 gynecologists were surgically active and eligible for inclusion in the study; the overall response rate was 74% (140/190). Of the initial survey respondents who were still alive and practicing at the time of second survey, 92% (107/116) responded to the follow-up. This represents 50% (28/56) of the eligible women and 59% (79/134) of the men of the original sample.

Results

Sample Characteristics

The mean rate of hysterectomies performed for the entire sample was 1.3 per month (SD = 1.3; range: 0, 6.7), with, on average, 1.4 performed by male gynecologists compared with 0.9 performed by female gynecologists (risk ratio [male/female] = 1.6; $P = .001$). Differences in other characteristics by sex are presented in Table 1.

Factors Associated with Hysterectomy Rates

Gynecologists who tended to perform hysterectomies at higher rates were male ($P = .001$), were further from training ($r = .26$; $P = .007$), practiced in areas with a lower density of gynecologists ($r = .25$; $P = .01$), and had a higher proportion of younger patients ($r = .26$; $P = .007$) and patients with abnormal bleeding ($r = .31$; $P = .001$) or cancer ($r = .25$; $P = .008$). In the multivariable model, the only physician factor that remained as a predictor of hysterectomy rate was year of residency graduation. Physicians' sex appears to be related to hysterectomy rates, which may be explained by differences in recency of training. Insurance reimbursement and type of practice are not predictive of hysterectomy rates. Recently trained gynecologists perform hysterectomies at lower rates than gynecologists who have been in practice longer, are more likely to believe that the uterus contributes to sexual function ($r = .26$; $P = .002$), and are less likely to believe that hysterectomy is generally more efficacious than medical management ($r = .33$; $P = .0002$). Physicians who practice in areas with a high density of gynecologists trained more recently ($r = .28$; $P = .004$) and are less inclined to believe that surgery is a better treatment than medicine ($r = .28$; $P = .004$).

Factors Associated with Appropriateness of Hysterectomy Ratings

Beliefs about the appropriateness of hysterectomy for the various clinical scenarios are related to several physician factors but are not related to hysterectomy rates (Table 2). Beliefs about the relative efficacy of hysterectomy are related to appropriateness ratings, but these beliefs are also not associated with higher hysterectomy rates.

Impact of Patient Preference

When patients expressed a desire to avoid surgery, physicians' ratings of the appropriateness of hysterectomy declined for all seven scenarios. This decrease was particularly prominent for scenarios concerning painful fibroids (mean difference = 3.1; $P = .001$), bleeding fibroids responding to treatment (mean difference = 2.3; $P = .001$), and cervical dysplasia (mean difference = 2.3; $P = .001$). Male and female gynecologists were similarly affected by a patient's expressed preference to avoid surgery.

Discussion

Some researchers have implicated a "physician factor" as a source of practice variation.[5,8–10] This may represent several sets of beliefs, which, in concert, may exert a more powerful effect on behavior than they do individually. Year of resi-

dency training, a major influence on physician practice style,[11] may serve as a proxy for numerous beliefs held by different cohorts of trainees about the uterus' contribution to sexual function and sexual identification, about surgery, and perhaps about other issues we did not measure. As noted, recently trained gynecologists have lower rates of hysterectomy, are less inclined to believe that hysterectomy is superior to medical management, and are more likely to believe that the uterus contributes to a woman's sexual functioning.

Socialization during training affects the formation and acquisition of professional beliefs and practices.[12] Within similar residency-year cohorts, female and male gynecologists did not differ in rates or ratings of hysterectomy, or in attitudes about the "uterus' contribution to a woman." The increasing number of women in obstetrics-gynecology may influence existing norms and account for our inability to detect sex differences. It is possible that women gynecologists have adopted their contemporaries' "male medical viewpoint" as the majority of gynecologists trained during these years are men.

Two practice factors are also important predictors of high hysterectomy rates: practice case mix and geographic location (i.e., physician-to-population density). Gynecologists with a higher percentage of patients with cancer or abnormal bleeding perform hysterectomies at higher rates. Although this correlation may simply reflect the increased need for hysterectomy among patients with significant symptoms or potentially dangerous diagnoses, it may also reflect a lower threshold for performing surgery among physicians exposed to more severe pathology.

We found that physicians who work in areas with fewer gynecologists perform hysterectomies at higher rates, and believe that surgery is a better treatment than medicine. These findings may reflect shared professional beliefs and community norms in specific geographic areas. Greater numbers of surgeons are not necessarily associated with higher rates of surgery.[9] Our study supports this. It is not necessarily the oversupply of physicians that affects hysterectomy rates; more likely, it is physician beliefs and attitudes, as these reflect community norms, that help determine variations in practice patterns.

Gynecologists' beliefs about the appropriateness of hysterectomy do not predict the rates at which hysterectomies are performed. This lack of association is consistent with other studies that have not found an association between appropriateness ratings and rates of cardiac angiograms, carotid endarterectomy, or gastrointestinal endoscopy.[13] This disjunction between ratings and rates provides support for particular physician factors (unmeasured in this study) rather than simply the appropriateness of a procedure influencing practice.

Greater satisfaction is found between female patients and female physicians than among other types of physician-patient dyads.[14,15] Researchers have found female physicians to be more sensitive than male physicians to issues of appropriate health care, contraception, hormone replacement therapy, abortion, and sex discrimination.[16–18] Some have speculated that increasing the number of women in medicine will make medicine more humane, particularly in the area of reproductive health.[19] It is somewhat surprising, then, that we did not find a difference by sex in physicians' ratings of appropriateness for the clinical scenarios, especially those in which women expressed a preference for avoiding surgery.

Patient preferences, doctor-patient communication, and physicians' beliefs about the efficacy of surgery are important factors in making treatment decisions for elective procedures.[2,20] Of all the factors we examined, a woman's expressed desire to avoid surgery had the greatest impact on lowering the appropriateness score. Social desirability in response to a clinical simulation may provide part of the explanation. Although appropriateness scores do not correlate with hysterectomy rates in this study, patients' expressed preferences could influence surgical referral. Patients concerned about undergoing possibly unnecessary surgery may want to seek opinions of gynecologists who have trained more recently. Perhaps even more important, patients should be encouraged to be open about their concerns and preferences for, or against, surgery when consulting with their physicians. □

TABLE 2—Factors Associated with Hysterectomy Ratings

Scenario	Mean Score (SD)	Associated Factors[a]	*P*
Cervical punch biopsy with dysplasia	4.8 (3.0)	. . .	NS[b]
Cervical cone biopsy with dysplasia	7.3 (2.2)	. . .	NS
Cancer fear in a woman with cancer risk factors	4.1 (2.5)	Residency year, attitude toward surgery, patients < 45 years old, MD sex	.0001
Bleeding fibroid refractory to iron treatment	8.6 (0.9)	Attitude toward surgery	NS
Bleeding fibroid responsive to iron treatment	6.5 (2.0)	Attitude toward surgery, patients with abnormal bleeding or cancer, MD sex	.001
Painful fibroid in otherwise healthy woman	7.5 (1.7)	Attitude toward surgery, patients with cancer, patients < 45 years old	.07
Painful fibroid refractory to medical treatment	8.3 (1.2)	Attitude toward surgery	.009

Note. The appropriateness scale for hysterectomy patients ranged from 1 to 9, with 1 = extremely inappropriate and 9 = extremely appropriate.

[a]Patients with abnormal bleeding = percentage of patients in physician's practice with abnormal bleeding; patients with cancer = percentage of patients in physician's practice with cancer. Based on multivariate analysis, linear model: appropriateness score of clinical scenario = % patients in practice with abnormal bleeding, % patients in practice with cancer, attitude toward surgery, population/physician density, physician sex, year of residency training, % practice < 45 years old.

[b]NS = not significant.

APPENDIX—Physicians' Beliefs Concerning Hysterectomy, Surgery, and the Importance of the Uterus

Importance of the uterus for sexual identification: Cronbach's alpha = 0.92
The uterus is important in making women feel
- feminine
- like other women
- normal
- self-esteem
- self-worth

Importance of uterus for sexual function: Cronbach's alpha = 0.84
The uterus is important in contributing to
- sexual functioning
- sensations during orgasm
- sexual responsiveness
- more health benefits than risks

Attitude toward hysterectomy and surgery: Cronbach's alpha = 0.66
- After hysterectomy, sex is more pleasurable for women.
- Hysterectomy is the best cure for pelvic pain.
- Pelvic pain is usually relieved with hysterectomy.
- Medicine is palliative; surgery is definitive.
- Surgery is more successful than medicine for relieving uterine pain.
- After hysterectomy, sex is more pleasurable for women's sexual partners.

Hysterectomy Use: The Correspondence between Self-Reports and Hospital Records

Kate M. Brett, PhD, and Jennifer H. Madans, PhD

ABSTRACT

Studies of the relationship between hysterectomy use and sociodemographic factors tend to use self-reported data. In the current study, data were collected from a representative sample of US women who have been prospectively followed since 1971. Hysterectomy status was obtained by self-report and from hospital records. Although these two measures of hysterectomy were highly related, more women reported hysterectomy than could be confirmed by hospital records. The two measures showed similar associations between several obstetric and demographic characteristics and hysterectomy status, suggesting that the use of self-reported hysterectomy data does not bias analyses of potentially associated factors. (*Am J Public Health.* 1994;84:1653–1655)

Introduction

Hysterectomy is the most commonly performed nonobstetric inpatient surgical procedure among women in the United States.[1] Several studies have attempted to identify factors associated with a greater likelihood of receiving this surgery in order to explain the variation in hysterectomy rates among industrialized countries.[2–8] The results have found hysterectomy to be associated with increasing age, lower education and family incomes, higher parity, and previous miscarriages. With the exception of one British study,[7] these studies have used self-reported hysterectomy information and could be affected by differential recall biases.

The purpose of this paper is to estimate the bias associated with self-report in analyses of hysterectomy. Using data from a prospective cohort study representative of the US population, we examined the correspondence between self-reported hysterectomy and hysterectomy confirmed by hospital records. We used hysterectomy rates and the association between hysterectomy and a number of socioeconomic and obstetric factors to estimate the potential bias introduced by the use of self-report.

Methods

Data were taken from the Epidemiologic Followup Study to the First National Health and Nutrition Examination Survey, a prospective investigation of 14 407 subjects 25 to 74 years of age who completed the First National Health and Nutrition Examination Survey (NHANES I) between 1971 and 1975. Follow-ups have been conducted from 1982 through 1984, in 1986, and in 1987.[9–11] We limited our analysis to Black or White women who, at the baseline survey, were between 25 and 34 years of age and reported having their womb. Women in this age group are unlikely to have had prior hysterectomy.[12] Of the 2104 Black and White women in the targeted age group, 2037 had intact uteri at baseline.

During the follow-up interviews, respondents were asked whether they had their womb and were requested to recount all hospital stays. Women were classified as reporting a hysterectomy if they reported the removal of their womb or if uterine cancer, hysterectomy (partial or full), or uterine removal was named as one of the causes of a hospitalization.

All hospitals named in the interview were contacted, if consent had been obtained, to obtain discharge summaries for all stays occurring during the interview period. Women for whom a hospital discharge summary was obtained listing hysterectomy in the procedures section (*International Classification of Diseases*, 9th edition, codes 68.3 through 68.7) were characterized as having a hospital-confirmed hysterectomy.

Agreement between the two hysterectomy measures was summarized by the kappa statistic.[13] Chi-square tests or *t* tests were used to compare the demographic and obstetric characteristics of women by hysterectomy status. Finally, proportional hazards models of hysterectomy involving each measure were estimated; these models incorporated covariates identified in previous research while accounting for differing lengths of follow-up among respondents.[14]

Results

Four hundred fifty-two respondents reported having had a hysterectomy, while 301 women had hospital-confirmed hysterectomies. Hysterectomy was coded on the hospital records of 3 women who did not report a hysterectomy. Conversely, 154 women reported having had a hysterectomy that could not be confirmed,

[d]Weight in kilograms divided by height in square meters.

although validation was not possible for 33 of these subjects because of problems in obtaining hospital records.

Comparisons between reported hysterectomies and hospital-confirmed hysterectomies yielded a kappa statistic of 0.75, which signifies fairly good agreement. However, because hospital records were obtained only if a hospital stay was reported, the kappa statistic primarily reflects the agreement between not reporting a hysterectomy and failure to obtain a hospital record of hysterectomy. Conversely, only 298 (66%) of the 452 reported hysterectomies could be confirmed.

Women reported their age at hysterectomy to be about 1 year younger than indicated by hospital records (Table 1). No other significant differences between the two groups of women categorized as having a hysterectomy were found. Compared with women who had either reported or hospital-confirmed hysterectomies, women who did not have a hysterectomy were younger at baseline, had fewer miscarriages, and were more likely to have had at least some college experience.

Multivariate models that used self-reported or hospital-confirmed cases as the outcome variable yielded very similar results (Table 2). Only age and high education were significantly associated with hysterectomy by both classification methods, while urban area of residence was related to hospital-confirmed, but not self-reported, hysterectomy.

Discussion

Most investigations of the relationship between hysterectomy use and demographic and obstetric characteristics have relied on self-reported information.[2,6,8] This study was able to incorporate information obtained through both self-report and hospital records. Twenty-five percent of women in the cohort reported ever having had a hysterectomy, while only 18% of the cohort had either a hospital-confirmed hysterectomy during follow-up or a self-reported hysterectomy prior to the baseline study. Estimates of rates based on hospital records in this study probably underestimate the true rates, since obtaining records was dependent on the respondents' ability to remember hospitalization information correctly, on obtaining consent for the record review, on securing the correct address for the hospitals, and on procuring assistance from hospital personnel in locating and summarizing all hospital stays.

Regardless of the source of information, women who had had hysterectomies were found to be older at baseline and to have less formal education than women with intact uteri. Only one variable, location of residence, was found to have a different relationship to hysterectomy by data source. Given the number of variables investigated, this difference is slight.

The similarity of analysis results may not apply to responses from women older than those included in this study or when the recall period is longer. We conclude from these data that associations obtained with self-reported hysterectomy information are not unduly biased. Although high reliability of hysterectomy self-reporting had been found previously,[15] the validity had not been established. Given these findings, it appears that investigations of the sociobehavioral characteristics associated with hysterectomy use will obtain valid results using either data collection method. □

Recruitment Activities and Sociodemographic Factors That Predict Attendance at a Mammographic Screening Program

Susan F. Hurley, PhD, Richard M. Huggins, PhD, Damien J. Jolley, MSc, and Dorothy Reading, BA

ABSTRACT

A random sample of 2266 women aged 50 to 69 years was used to investigate factors that predict attendance at a free Australian mammographic screening program. The most important predictor was receipt of a personal invitation letter. A letter that included an appointment time increased attendance 132-fold initially and decreased to 20 times baseline after 14 days. A letter that did not include an appointment time increased attendance 12-fold, and a second letter to nonattenders increased attendance approximately 13-fold. Attendance declined with increasing distance from the program and with increases in the percentage of non-English speaking women in a neighborhood, but was higher in areas of higher socioeconomic status. (*Am J Public Health.* 1994;84:1655–1658)

Introduction

Women's adherence to recommended mammography screening schedules often is suboptimal,[1] and development of strategies that maximize participation is necessary for mammography to achieve its potential for breast cancer control.[2] We evaluated the impact of recruitment strategies and sociodemographic factors on attendance at the Essendon Breast X-ray Program, a pilot project conducted in the state of Victoria, Australia.

Methods

Target Population and Recruitment Strategies

During a 2-year period, the Essendon program offered free screening and consequential assessment to 43 771 women aged 50 to 69 years. These women lived in any of 34 surrounding postcode areas and were listed on the electoral roll,[3] for which enrollment is nominally compulsory.[4]

TABLE 1—Attendance and Selected Sociodemographic Characteristics of the Sample, by Invitation Type

	No Letter (n = 832)	Letter A (n = 424)	Letter B (n = 1010)
Percentage who attended			
Before letter campaign	16.6	. . .	. . .
Total	43.8	40.1	26.6
Mean age in years (SD)			
Attenders	57.4 (5.9)	57.3 (5.8)	56.9 (5.6)
Nonattenders	59.5 (7.3)	58.2 (5.9)	57.7 (6.1)
Mean Indicator of Disadvantage[a] (SD)			
Attenders	99.1 (5.9)	96.5 (6.6)	98.6 (6.2)
Nonattenders	96.9 (5.8)	95.7 (6.2)	97.1 (6.7)
Attendance profile, %			
Attended after first letter	. . .	35.1	9.1
No further invitation	. . .	22.6	12.8
Follow-up letter and attended	. . .	5.0	17.5
Follow-up letter and did not attend	. . .	37.2	60.6

Note. Letter A included a specific appointment time, Letter B did not. The follow-up letter after Letter A or Letter B did not include a specific appointment time.

[a]The Indicator of Disadvantage was scored to have a median value of 100 for Australia. In the state of Victoria, the value ranged from approximately 80 to 120. For postcodes within the target area, the median was 96.2, mean was 97.7, and range was 84.5 to 113.7.

TABLE 2—Predictors of Attendance, from the Cox Proportional Hazards Model

Recruitment Activities and Sociodemographic Factors	Relative Risk[a]	95% Confidence Interval
Distance (km)[b]	0.97	0.966, 0.994
Percentage non-English speaking	0.99	0.988, 0.997
Indicator of Disadvantage[c]	1.03	1.02, 1.04
Letter A		
7–14 days	132	103, 170
15–42 days	19.6	12.5, 30.7
> 42 days	3.18	2.03, 4.99
Follow-up letter after Letter A		
1–49 days	1.56	0.70, 3.39
> 49 days	0.75	0.35, 1.63
Letter B		
1–42 days	12.2	9.2, 16.1
> 42 days	4.98	3.37, 7.36
Follow-up letter after Letter B		
1–49 days	13.25	3.62, 48.7
> 49 days	1.15	0.69, 4.96

[a]Each relative risk is adjusted for age and age squared as well as for the other variables in the table. Regression coefficients (standard errors) for age and age squared were 0.4056 (0.1295) and −0.364 (0.1120), respectively.

[b]The risk of attendance for a woman who lived 15 km from the program relative to a woman who lived 5 km from the program was $(0.97)^{10} = 0.74$ (i.e., a reduction of 26%).

[c]The risk of attendance for a woman living in a postcode with a value of 105 for the Indicator of Disadvantage (the 75th percentile for the target area) relative to a woman living in a postcode with a mean value of 93 (the 25th percentile for the target area) was $(1.03)^{12} = 1.43$ (i.e., 43% higher).

There was considerable diversity in socioeconomic status and ethnicity within the target area.

Both public and personal recruitment strategies were used to get the women to participate in the program. The public campaign included articles in local newspapers (delivered free to each home); community promotion (displays of multilingual information, establishment of appointment stalls in public places, and contact with community, workplace, and health information organizations by an education officer); and promotion of the program to primary care physicians by an education officer.

The personal campaign consisted of invitation letters sent to randomly selected women who had not attended. The women received either a letter stating a specific appointment time (Letter A) or a letter without a stated appointment time (Letter B). Random samples of women who had not attended or had not made an appointment 4 weeks after receiving the first letter were sent a follow-up letter without an appointment time. An information brochure and details of an interpreter service that was willing to translate the letter in five languages were included.

The three public strategies began at the start of the program, and at fairly low intensity, to give women who were motivated to attend the opportunity to do so. The invitation letter campaign began in the sixth month, and, thereafter, both personal and public recruitment strategies were used.

Analysis of Attendance

A random sample of 2266 women was selected. The sample was stratified by postcode of residence, 5-year age group, and invitation type (no letter, Letter A, and Letter B). We developed a multivariate survival model in which attendance for mammography was regarded as failure and observations of time until attendance were regarded as censored if a woman either turned 70 years of age, or died, or the program ended before the woman attended. The Cox proportional hazards regression model was used,[5] and analyses were performed with the P2L procedure in BMDP.[6] The proportional hazards model allows estimation of the risk of attendance for women with specific values of covariates (predictor variables) relative to the risk of attendance for women with different values of these variables. Covariates may be time-dependent (i.e., their value changes over time).

We investigated the following potential predictors of attendance: age; four postcode-level sociodemographic variables (distance from program, mean travel time by public transportation, the percentage of women who spoke a language other than English at home, and a census-based measure of socioeconomic status known as the Indicator of Disadvantage[7]); postcode-level variables summarizing the intensity of public recruitment activities

(number of local newspaper articles per month, hours of community promotion per month, and hours of promotion to physicians per month); and time-dependent variables based on the time in which invitation letters were sent.

Results

Attendance patterns are summarized in Table 1. On average, women who attended the program were slightly younger than nonattenders and lived in areas of higher socioeconomic status. Of women who were not sent an invitation letter, 43.8% attended, compared with 40.1% of women who were sent Letter A and 26.6% who were sent Letter B. Letter A plus a follow-up letter to nonattenders resulted in attendance of 42.7%, whereas attendance was 29.5% in the sample who received Letter B plus a follow-up letter to nonattenders. However, such simple comparisons of attendance rates are potentially misleading. Although the group that received no letter had the highest attendance rate, this does not mean that the public campaigns were effective, because 38% of the women from this group who attended did so when the public campaigns operated at low intensity and before the letter campaign began. These women were motivated to attend without having been exposed to recruitment campaigns. As the program progressed, women from the pool of women who had not attended were selected to receive an invitation letter.

The final Cox model is summarized in Table 2. Age and age squared were included because attendance rates increased with age until around the age of 56 years and then declined. The model suggests that a woman's risk of attending declined by approximately 3% in a multiplicative manner for every additional kilometer her postcode was located from the program and declined by 1% for every percent of the postcode's female population 50 to 69 years of age that spoke a language other than English at home. The relative risk for the Indicator of Disadvantage suggests that attendance was greater in postcodes with higher socioeconomic status, increasing by approximately 3% for every unit of the index.

After women received Letter A, attendance rates increased 132-fold in the first 7 to 14 days, then dropped to approximately 20 times baseline for 15 to 42 days and to approximately 3 times baseline after 42 days. The relative risk of attendance after receiving the follow-up letter after Letter A was 1.56 initially, dropping to 0.76 after 49 days, but the confidence limits indicate that attendance rates for women who received these letters did not differ significantly from baseline. Nevertheless, these variables were included in the model to provide a full description of the impact of personal invitations on attendance rates over time. After women received Letter B, attendance was 12 times baseline initially, dropping to approximately 5 times baseline after 42 days. A follow-up letter after Letter B increased attendance rates 13-fold initially (higher than the response to Letter B itself), but after 49 days attendance did not differ significantly from baseline. Variables summarizing the intensity of the three types of public recruitment were not statistically significant.

Discussion

Our findings regarding sociodemographic predictors are consistent with previous reports. A decrease in attendance with increasing distance from the screening site also was reported for a mobile service in the United Kingdom,[8] and the New York Health Insurance Plan trial found that women with shorter travel times were more likely to attend repeat screenings.[9] The lack of effect of public transportation travel time on attendance is not surprising, because 74% of women traveled to the program by car.[10] Cultural factors may have made women from non-English speaking backgrounds less motivated to attend, or the promotional material may have been less accessible, despite efforts to minimize this possibility. The lower attendance rate associated with living in a postcode with lower socioeconomic status is consistent with previous reports of lower participation for poorer and less educated women.[1,11]

The response to an invitation that included an appointment time was much higher than the response to a letter without a specific appointment time, a similar finding to a United Kingdom study.[12] However, an earlier analysis of data from our program showed that due to higher costs associated with Letter A, the most cost-effective recruitment strategy was a Letter B with a follow-up letter to nonattenders.[13]

Our analysis did not detect any effect of the public recruitment campaigns. In a previous analysis, Poisson regression analysis was used to investigate the role of public recruitment campaigns on postcode attendance rates early in the program for women who had not received a letter. No effect of promotion to physicians was detected, but local newspaper articles and community promotion did increase attendance rates.[13] Other studies have found that a doctor's recommendation increases participation in screening mammography,[1,14] and in the early phases of our program, 39% of women in a sample of 130 attended following their doctor's recommendation.[15] However, after education staff visits, doctors seemed only to encourage their patients to attend for short periods, perhaps explaining the overall lack of effectiveness of physician promotion. A similar lack of success in getting physicians to alter practice patterns in a community-wide intervention study was reported by Fletcher et al.[16]

The cause of the difference in results between our current and previous analyses regarding local newspaper articles and community promotion may be the fact that previous analysis considered only the first 16 months of the program or the fact that earlier analysis was based entirely on postcode-level predictors and attendance rates, whereas, in the current analysis, data on attendance and receipt of letters were available for individual women, but public recruitment information only was available at a postcode level. The large impact on attendance of a woman's receipt of an invitation letter is likely to have obscured any effect of promotion of the program within the woman's neighborhood.

Despite these limitations, our study has provided a useful description of factors that predict attendance in an Australian program. The most important predictor of attendance was receipt of an invitation letter, and attendance varied markedly with the type of letter. The Cox regression model may be useful for evaluation of other public health programs. □

The Accessibility of Drug Treatment for Pregnant Women: A Survey of Programs in Five Cities

Vicki Breitbart, MSW, Wendy Chavkin, MD, MPH, and Paul H. Wise, MD, MPH

ABSTRACT

Through simulated calls to 294 drug treatment programs in five cities, this study investigated access for pregnant women and compared New York City's provision of services in 1989 to that in 1993. In all sites, the majority of programs accepted pregnant women. There was also a marked improvement in the availability of services in New York City. Yet options were more limited for Medicaid recipients and women needing child care, and an appointment or referral for prenatal care was usually not offered. Although the door for treatment may be opening for pregnant women, institutional barriers still remain. (*Am J Public Health.* 1994;84:1658–1661)

Introduction

Recent reports estimate that as many as 8 million American women of childbearing age are using illicit drugs.[1] From 1986 to 1988 there was a documented 50% increase in the number of drug-exposed infants.[2] The responses to this crisis have been diverse. By 1992, 14 states had passed legislation promulgating substance abuse treatment or coordination of services for women.[3] However, 24 states have criminally prosecuted women for using drugs during pregnancy. The number of women prosecuted, who are mostly poor and African American, tripled between 1990 and 1992.[4]

Proponents of prosecution argue that addicted women must be compelled to seek treatment.[5,6] Yet in 1989, Chavkin conducted a simulated caller survey of drug treatment programs in New York City and found that more than half of the programs categorically excluded pregnant women and that the overwhelming majority refused treatment to crack-addicted women on Medicaid.[7] Targeting programs in five cities (including New York City), this present study similarly used simulated calls to assess whether exclusion based on pregnancy, method of payment, or the need for child care is widespread and whether it still prevails in New York City today. There are many complex factors that deter pregnant women from seeking substance abuse treatment; this survey focuses on major institutional barriers.

Methods

Site Selection

In addition to New York City, the sites for this study included Albuquerque, NM; Charleston, SC; Detroit, Mich; and Portland, Ore. They were selected on the basis of their geographic and demographic diversity, and their common concern with the issue of perinatal drug exposure. All the sites had conducted prevalence studies or had documented substance abuse by pregnant women.

Vicki Breitbart and Wendy Chavkin are with the Center for Population and Family Health at the Columbia School of Public Health, New York, NY. Paul H. Wise is with the Harvard Institute for Reproductive and Child Health and the Joint Program in Neonatology, Harvard Medical School, Boston, Mass.

Requests for reprints should be sent to Vicki Breitbart, MSW, Center for Population and Family Health, Columbia University, 60 Haven Ave B-3, New York, NY 10032.

This paper was accepted on March 16, 1994.

These sites also represent varied policy approaches toward the problem of drug use among pregnant women. Whereas Oregon has legislation that protects women against prosecution for drug use during pregnancy,[8] all the other sites are in states that have criminally charged women for using drugs during pregnancy.[4,8] In New York, after a dramatic upsurge in the number of "boarder babies" (drug-exposed infants in the hospital awaiting disposition by Child Protective Services), the State Department of Social Services altered the protocol regarding positive neonatal toxicology results. Drug exposure is still grounds for a report to Child Protective Services, but a full investigation must now assess parental fitness.[9]

Charleston has instituted a collaborative program between the obstetrical service in the university hospital and local law enforcement agencies, whereby any woman who presents for prenatal care and tests positive for drugs is reported to the local solicitor. Forty warrants have been issued to drug-using pregnant women, resulting in 25 arrests[10] (personal communication, Shirley Brown, Medical University of South Carolina, December 2, 1992). In contrast, university-based pediatricians, in Albuquerque, together with the local district attorney, established a program to provide treatment for any woman who is arrested and found to be addicted and pregnant.

Survey Questionnaire

A list of all the substance abuse treatment programs in each city was obtained from the state agency regulating drug treatment. Drug treatment experts in each site provided information about the local terminology and substance abuse pattern, which was incorporated into a script for the callers. Each caller described herself as 5 months pregnant, not receiving prenatal care, addicted, on Medicaid, and the mother of a 15-month-old child. She requested child care and recorded whether the program provided or arranged for the service. However, because many drug-using women do not seek prenatal care,[11] the caller did not try to solicit this service. Instead, she clearly stated that she had not received any prenatal care prior to the phone call and recorded every time she was either told that the program would provide such care on site or given a referral.

Callers identified themselves as seeking substance abuse treatment and talked to the receptionist or intake worker who provided admissions information. Two calls were made to every program, each by a different caller. If the information differed between the calls, a third call was made and the most frequent answer was selected. In all cases where the service was provided for free, it was added to the group that accepted Medicaid.

Results

In all, the survey included a total of 294 programs, although the number of programs in each city varied partly as a function of city size. Percentages presented here are based on the number of facilities that provided complete information in a category.

The majority of outpatient and residential programs—ranging from 64% of all programs in Detroit to 100% of all programs in Albuquerque and Charleston (Table 1)—accepted pregnant women. Method of payment, however, proved to limit access significantly. While all the outpatient programs in Albuquerque and Charleston accepted pregnant women, fewer of these programs accepted pregnant women on Medicaid (50% and 71%, respectively). This pattern prevailed in the outpatient programs in the other sites as well. Access to residential programs also decreased for women on Medicaid in all the sites; in Albuquerque, there was only one residential treatment program that accepted pregnant women, and it did not accept a Medicaid recipient.

If the woman was seeking child care, her options for drug treatment were severely restricted. Three quarters of the outpatient programs in New York City accepting pregnant women did not provide child care (Table 1). Child care was even less available at the other sites. Callers found no outpatient programs in Charleston and no residential or detoxification programs in Albuquerque, Charleston, or New York that responded to their child care needs.

More programs treating crack addiction were willing to accept pregnant women than were those treating heroin addiction—90% as compared with 73% (Table 2). Similarly, a higher proportion of programs accepting pregnant women and treating crack addiction accepted Medicaid (80%) than did those treating heroin (65%) or alcohol addiction (58%). More than a quarter of the crack programs accepting pregnant women provided child care, whereas the heroin and alcohol programs offered child care less than 20% of the time. Finally, although the callers clearly stated that they were pregnant and had not received prenatal care, in most instances the program

respondent did not provide an appointment or a referral for medical care.

Comparison of data from the two surveys of New York City programs indicated a dramatic shift between 1989 and 1993. Eighty-two percent of that city's programs accepted pregnant women in 1993 whereas only 46% had done so in 1989 (Table 3). There was also a marked change in every program parameter examined. More accepted Medicaid, more provided or referred for prenatal care, and more provided or arranged for child care, even though only one quarter of all facilities responded positively to this last request.

Discussion

In the five cities surveyed, the majority of substance abuse treatment programs accepted pregnant women. For New York City, this represents a significant increase in available services. We can only speculate as to whether this change resulted from legal pressure (there was a class action suit on behalf of women denied access to treatment because of pregnancy),[12] the availability of funds

from the state and federal government earmarked for this population, funding regulations and mandates, heightened awareness, or other factors. The data do demonstrate that New York City drug treatment programs have substantially altered their behavior toward pregnant women during these 4 years and are currently more likely to accept pregnant women. On the other hand, treatment options declined in all sites if the woman was a Medicaid recipient. Such differential access to treatment based on mode of reimbursement underscores the importance of including drug treatment services in the design of a national health care reform package.

Recent federal regulations for substance abuse treatment stress the importance of prenatal care and child care.[13] This study found little programmatic recognition of the client's need for these services. Prenatal care has been documented to have a beneficial impact on the birth outcomes of substance-abusing women.[14] Yet most staff who responded to our callers seemed unaware of the urgency of such a referral for a pregnant woman in her second trimester without medical care. More than a decade ago, researchers reported that lack of child care precluded addicted women's participation in treatment.[15] Unfortunately, this part of the picture has not changed; only a small proportion of programs make child care available.

Although the treatment door is now open to pregnant women, institutional barriers are still widespread, preventing poor women with children from getting care. Criminal prosecution and other similar policies that target the individual behavior of drug-using women implicitly discount the systemic inadequacies documented here. □

First Russian-American Breast Cancer Conference to Be Held

The first Russian-American Breast Cancer Conference will be held in Saratov, Russia, June 7–9, 1995. Organized to facilitate the sharing of information on advances in breast cancer diagnosis, treatment, and prevention, the conference is sponsored by the National Cancer Institute of the National Institutes of Health, US Department of State, National Alliance of Breast Cancer Organizations, University of North Carolina School of Medicine, Saratov Medical University, and Russia's National Oncology Center in Moscow. Nearly a dozen leading breast cancer experts from the United States will join specialists from throughout the former Soviet Union as conference leaders.

Although this conference was created primarily to update the Russian medical community, interest by North American and Western European physicians resulted in opening the conference to these physicians as well. This conference ends a half-century of seclusion for most doctors in the former Soviet Union from western scientific and medical development.

Conference arrangements are being coordinated by Svetlana Lisanti, President, Center for Bio-Medical Communication, Inc., Dumont, New Jersey. Additional conference information can be obtained by calling the center at (201) 385-8080.

National and State Spending on Specialty Alcoholism Treatment: 1979 and 1989

Joyce H. Huber, PhD, Gregory C. Pope, MS, and Debra A. Dayhoff, PhD

ABSTRACT

The National Drug and Alcohol Treatment Unit Survey was used to measure changes in specialty alcoholism treatment spending between 1979 and 1989 nationally and by state. National spending more than doubled from $1.6 billion to $3.8 billion in 1989 dollars. Private spending increased more rapidly than public spending, although most clients continue to be publicly funded. Dramatic differences across states in public funding growth were partially explained by differential increases in per capita income and in federal substance abuse block grants. Access to treatment continues to vary widely across the states. (*Am J Public Health.* 1994;84:1662–1666)

Introduction

During the 1980s, the financing of alcohol abuse treatment experienced a transformation in both the private and the public sectors. There was a dramatic increase in private third-party coverage of substance abuse treatment. In 1979, 17 states had legislation mandating that alcoholism treatment be offered by insurers as a benefit or an optional benefit.[1] By 1988, all but 10 states had enacted such legislation. Between 1981 and 1988, insurance coverage of alcohol abuse treatment increased from 36% to 83% of employees at medium and large private firms.[2]

Federal funding for substance abuse also underwent a transformation. Before 1982, the federal government funded substance abuse treatment through a series of categorical grants that targeted particular programs or populations. In 1982, these categorical grants were consolidated into the Alcohol, Drug Abuse, and Mental Health Services block grants, which are administered by the states. The initial 1982 block grant reduced funding by 25%.[3] Between 1985 and 1989, there was a real increase of 75% in federal block grant funds, including both the Alcohol, Drug Abuse, and Mental Health grants and the Alcohol and Drug Treatment and Rehabilitation grants.[4,5]

This paper compares funding and use of alcoholism treatment at specialized facilities in 1979 and 1989 to measure the changes resulting from the spread of private insurance coverage and consolidation of federal funding into the block grants.

Data and Methods

The primary data used for this study were the 1979 and 1989 National Drug and Alcoholism Treatment Unit Surveys, censuses of substance abuse treatment units sponsored by the National Institute on Alcohol Abuse and Alcoholism and the National Institute on Drug Abuse. In these surveys, all known facility-based units are requested to provide total annual funding for alcoholism and drug abuse treatment by source of funds, as well as capacity and number of clients treated on a particular date by modality (e.g., detoxification, rehabilitation) and setting (e.g., inpatient hospital, inpatient nonhospital, outpatient). Three types of treatment settings are not included in the surveys: treatment in nonspecialty beds of general hospitals, office-based treatment by private practitioners, and treatment through self-help groups such as Alcoholics Anonymous. These other settings, particularly self-help groups, may represent a substantial proportion of treatment for substance abuse or its problems.[6]

To improve estimates of total spending in 1979 and 1989, we imputed missing values for funding and used nonresponse weights to inflate our 1979 and 1989 funding, client, and capacity estimates. Missing values for funding were set to mean funding per unit capacity by ownership category (e.g., private for-profit, private nonprofit) and location (e.g., community mental health center, general hospital). We inflated funding, client, and capacity levels to compensate for survey nonresponse. In 1979, the overall response rate was 93.4%, but it dropped to 78% in 1989. There is no information for the 1979 survey on response rate by state or ownership type; therefore, we used the national nonresponse rate to inflate funding, capacity, and clients. We used state-specific nonresponse rates from 1989 and information on public and private nonresponse from a 1990 nonresponse survey[7] to adjust the 1989 levels.[8] All 1979 dollars were inflated to 1989 dollars by means of the Consumer Price Index. While nonresponse adjustments should produce accu-

This paper was accepted April 18, 1994.

Note. The views expressed are the authors' and do not necessarily represent the views of the National Institute on Alcohol Abuse and Alcoholism.

rate estimates of national growth in alcoholism treatment, they may result in biased estimates of growth in those states or ownership categories whose 1979 response rates differed substantially from the national response rate.

In the National Drug and Alcoholism Treatment Unit Survey, individual clients cannot be identified as publicly or privately funded. Clients in units with more than 75% of their funding from public sources were considered publicly funded clients, whereas clients in units with more than 75% of their funding from private sources were considered privately funded clients. If facilities received between 25% and 75% of their funding from public sources, clients were designated as publicly or privately funded in proportion to the funding from each source.

Results

National Trends in Alcoholism Funding and Clients at Specialty Treatment Units

The recognition of alcohol abuse as a serious, but treatable, medical and public health concern is reflected in changes in the levels and sources of funding between 1979 and 1989. Between 1979 and 1989, real spending on alcoholism treatment at specialty units more than doubled from $1.6 billion to $3.8 billion (Table 1). Private funding grew more rapidly than public funding, rising from one third to one half of the total. There was also a shift in both the private and public sectors to third-party funding. In 1979, public and private third-party insurance together accounted for about one quarter (28%) of total spending; by 1989 it accounted for nearly half (48%). Private third-party spending grew the most rapidly of any major category, as private insurance coverage for alcoholism treatment spread. Such spending accounted for $1 billion, or nearly half, of the $2.2 billion spending increase over the decade. Despite recent expansion of federal support for substance abuse funding through block grants, state-administered categories, including federal grants, have been the slowest growing of the major funding categories. However, the decreased importance of state and federal funds is partially offset by the increased importance of public third-party funding (primarily Medicaid). The shift away from alcoholism treatment as a welfare or philanthropic activity toward a medical insurance model of alcoholism treatment funding is reflected in both the increase in third-party funding and the erosion of the vestiges of funding from private donations and public welfare, which fell from 9% to 2.5% of total funding.

Note. The table reflects the number of clients in treatment on April 30, 1979, and September 30, 1989. Adjustments were made for nonresponse and missing data.
[a]The main modalities were medical detoxification, social detoxification, and rehabilitation and recovery, sometimes referred to simply as alcoholism treatment.
[b]Other refers mainly to individuals whose location of treatment was a correctional facility. Clients in this category are not strictly comparable because of differences between the 1979 and 1989 survey forms.

TABLE 3—Public and Private Spending on Alcoholism Clients at Specialty Treatment Units, 1979 and 1989 (in 1989 Dollars)

State	Public Spending Per Capita, $ (Rank)			Private Spending Per Capita, $ (Rank)		
	1979	1989	Change, %	1979	1989	Change, %

Note. Adjustments were made for nonresponse and missing data.

State and local governments still predominantly fund treatment through programmatic grants but are relying more on fee for service reimbursement, perhaps to encourage greater accountability and productivity in treatment programs. Specialty alcoholism treatment remains heavily subsidized to individuals with only 9% and 12% of total funds coming from client fees in the 2 years.

The increase in real funding resulted in more access to treatment and greater intensity of treatment. The number of clients receiving treatment on a typical day rose from about 300 000 to about 500 000, a 67% increase (Table 2). Privately funded clients more than tripled, in comparison with a modest increase of 27% in publicly funded clients. However, on a typical day in 1989, the public sector still funded treatment for 50% more clients than the private sector. In 1979, 79.5% of clients were seen in outpatient settings; in 1989, 86.4% of clients were seen in such settings (Table 2). Correspondingly, the percentage of patients seen in both inpatient hospital and residential facilities has fallen.

Intensity of service, as measured by real spending per client-day, increased by 42% (from $14.35 in 1979 to $20.37 in 1989), in large part as a result of the relative shift of clients to the private sector, which provides more expensive treatment. In 1979, real spending per client-day was $11.66 for publicly funded clients, in comparison with $26.47 for privately funded clients. By 1989, spending per client-day had risen to $15.55 for publicly funded clients and $28.29 for privately funded clients, increasing 33% in the public sector and 7% in the private sector. Most of this differential spending growth can be attributed to a relatively greater growth of less costly outpatient treatment in the private sector. However, another part of the explanation may be a movement of individuals who are more treatable—those employed and with private health insurance—to the private sector, leaving only the more serious and costly cases in the public sector.

State Variations in Growth of Spending on Alcoholism Treatment at Specialty Units

Individual states have deviated considerably from national trends (Table 3). Despite significant growth nationally, 2 states experienced negative growth in private spending per capita, and 14 states experienced negative growth in public spending per capita. Six western states that were national leaders in 1979 saw public spending per capita fall by 19% to 36%: Oregon, California, Wyoming, Colorado, Idaho, and Montana. Two of these states, Idaho and Wyoming, had among

the highest growth rates in private spending per capita.

California experienced a 23% decrease in real public spending per capita and a 40% drop in publicly funded clients per capita (data not shown). California also had a below average increase in real private spending per capita. Consequently, the state fell from above to below the national average in alcoholism treatment funding per capita. The decrease in real public funding for alcoholism treatment can be largely attributed to a 66% drop in real local spending and a 41% drop in real public third-party (mostly Medicaid) spending. It seems likely that the California tax revolt, exemplified by Proposition 13, had a detrimental effect on alcoholism treatment spending.

Several states, on the other hand, made substantial gains in public financing of alcoholism treatment (e.g., New Jersey, Iowa, Oklahoma, New York, Maryland, and Rhode Island). New York evidenced a 174% increase in real public spending per capita, which was the fourth highest percentage increase in the country. Real public spending in New York rose from $121 million in 1979 to $338 million in 1989 and accounted for 34% of the national increase in public spending on alcoholism treatment (in comparison, the state comprises 7% of the nation's population). New York moved from 12th to 2nd in public spending per capita. Public third-party spending, primarily Medicaid, rose 307% from less than 3% of public spending on alcoholism treatment in 1979 to 46% in 1989. In a deliberate policy to use Medicaid to finance substance abuse treatment, New York expanded Medicaid coverage to individuals and services beyond federal eligibility requirements and foregoes federal matching funds for these individuals and services.[9]

Changes in state spending across the decade did not increase overall equity across states. Private spending per capita became more equitable, with the ratio of private spending per capita in the highest spending state to that in the lowest spending state falling by two thirds. However, variation in public spending per capita and total spending per capita (as measured by the coefficients of variation and the ratios of high to low) did not change significantly between 1979 and 1989. The federal block grant did not reduce the inequity across states in public funding per capita. The initial distribution of the block grant funds was based on historical funding levels. Although the allocation formula was revised several times to include states' measures of population and "need," these revisions applied only to incremental funding (most notably the Alcohol and Drug Treatment and Rehabilitation supplement established in 1987). Growth in nominal funding of the block grant was so low between 1979 and 1989 that the need-based incremental allocations had no distributional impact. Thus, there remained in 1989 considerable disparity across states in spending per capita, particularly for publicly funded clients.

TABLE 4—Regression of Changes in State/Local Government Funding for Alcoholism Treatment on Explanatory Variables

	Coefficient	*t*
Intercept	0.15	0.19
Change in per capita income[10,11]	0.54	3.11**
Change in per capita alcohol consumption[a,12]	1.26	1.16
Change in block grant 1985–1989[4,5]	0.80	1.79*
Mandated private insurance coverage of alcoholism treatment[1]	0.36	0.52
Adjusted R^2 = .20		
n = 50		

Note. All financial variables were measured in 1989 dollars. The dependent variable was change in state/local government spending on alcoholism treatment at specialty units, 1979–1989 (including federal grants to state and local governments), excluding Alaska.

Source. The original data on alcoholism treatment spending is from the National Drug and Alcoholism Treatment Unit Survey. The sources of original data for the remaining variables are indicated by the reference numbers.

[a]Other variables measuring change in need (i.e., rates of cirrhosis deaths, motor vehicle accidents, and alcohol-related arrests) were also included but had no effect on the growth of public spending on alcoholism treatment.

*$P < .10$; **$P < .01$.

Factors Influencing Growth of Public Spending on Alcoholism Treatment

Multivariate regression was used to examine factors that influenced growth in per capita state/local government spending on alcoholism treatment between 1979 and 1989 (Table 4). All state-administered spending, including federal substance abuse grants, was incorporated in the dependent variable. Enactment of mandated private insurance coverage of alcoholism treatment between 1979 and 1989 and change in alcoholism consumption per capita did not have a significant effect on public treatment spending. Conversely, each $1000 increase in real per capita income raised real per capita state/local government spending on alcoholism treatment by a statistically significant $0.54. Because higher federal grants may cause state governments to reduce their own appropriations, greater block grant funding does not necessarily raise total state-administered spending. However, the significant regression coefficient of .8 indicates that a $1.00 increase in the federal substance abuse block grant increased state-administered spending on alcoholism treatment by $0.80.

Conclusions

This paper has documented a dramatic increase in spending on specialty alcoholism treatment between 1979 and 1989, from $1.6 billion to $3.8 billion in 1989 dollars. The rate of spending growth has probably slowed in the early 1990s as many state and local governments have entered a period of fiscal crisis. In addition, third-party payers have reduced allowable reimbursements for substance abuse treatment, especially inpatient stays.

Funding for substance abuse treatment has been moving gradually toward an insured medical disease model. This trend may be brought to completion if substance abuse treatment benefits are included in the minimum benefits package for national health reform. Universal insurance coverage would be expected to raise overall spending on specialty substance treatment and the number of clients in treatment and to reduce inequities in access to care among the states. □

Monitoring Childhood Immunizations: A Canadian Approach

Janice D. Roberts, MB, MSc, Linda A. Poffenroth, MD, MSc, CommMed, Leslie L. Roos, PhD, Judith D. Bebchuk, MSc, and Anne O. Carter, MD

ABSTRACT

In Manitoba, Canada, a centralized, computerized childhood immunization monitoring system serves a population with insured medical coverage; each individual has a unique identification number. All physicians bill a single payer, and specific billing codes are used to identify immunizations given by physicians and by public health nurses. Together with dates of service, this information is used to construct immunizations-to-date and age-at-immunization profiles for individuals and groups. Reminders seeking missing information are built into the system and executed at strategic ages. The quality of input data has been assessed as high. The approach could be used readily by health maintenance organizations in the United States (*Am J Public Health.* 1994;84:1666–1668)

Introduction

The immunization program in Manitoba, Canada, is supported by a computerized information system (the Manitoba Immunization Monitoring System) that both measures and augments coverage among an entire population of children. The system is challenged by demography and delivery. While half the province's population of 1.1 million lives in Winnipeg, the remainder is scattered throughout rural and remote areas across 780 000 km^2 (300 000 square miles) and includes the residents of more than 60 Indian reserves. Except for Indians with treaty status, the provincial government is the single payer in a system of universal health insurance. Care for treaty-status Indians is the fiscal responsibility of the federal government. Three levels of government—municipal (city of Winnipeg), provincial, and federal—and two types of providers—physicians (80%) and public health nurses (20%)—are involved in the delivery of immunizations. Among children 14 years of age and under, we estimated that about 16% moved within Manitoba annually, while from 4% to 5% migrated into or out of the province.

Given the high level of American concern over immunization rates and their measurement, this paper offers a timely description of the Manitoba system and examples of the types of output available.

Methods

The Manitoba Immunization Monitoring System

Implemented in 1988, the Manitoba Immunization Monitoring System was constructed on the virtually complete population registry through which the province's health plan is administered; eligibility depends on registration. The

Editor's Note. See related editorial by Bernier (p 1567) in this issue.

computerized registry file includes, for each individual, a unique identification number, demographic identifiers, and dates of commencement and termination (migration out of the province or death) of plan enrollment. The file is regularly and automatically updated from the registration of adoptions, births, and deaths and from notification of migration into and out of Manitoba.

Children born on or after January 1, 1980, are automatically entered into the system at registration. The system file contains, for each child, registry data and the immunization record: four-digit codes identifying the (generic) vaccines administered and their sequence in the recommended immunization schedule, service dates, and the presence or absence of restrictions (to record vaccine contraindications).

Each child is assigned (by means of municipal and postal codes) to the public health office in the area of residence. Information concerning public health nurse immunizations is entered directly through terminals in all jurisdictions. Immunization data are transferred electronically to the system file from physician billing claims submitted to the health plan. Claims identify services (e.g., office visit, immunization) by tariff codes. Immunization codes represent vaccine type and sequence schedule (Table 1).

Immunization status is monitored by comparing, in the month of the first, second, fifth, and sixth birthdays, the system record and the recommended schedule. Missing or incorrectly coded immunizations produce a letter to the family (fifth birthday) or the provider (other birthdays) requesting correction or completion. "Reminders" are distributed through public health offices with amended records returned for data entry. Children whose records remain incomplete are actively followed by public health offices and offered immunization. Since the federal health department did not participate in the Manitoba Immunization Monitoring System until 1990, the records of Indian children have been considered incomplete and not yet monitored.

Comparisons between physician and system records have shown excellent agreement, with 2% or fewer immunizations coded incorrectly and service dates matching 98% of the time. The rate of physician failure to bill has been estimated at between 0.2% (urban) and 6.6% (rural). A direct examination of the efficacy of monitoring estimated that, among 1- and 2-year-olds, monitoring increased coverage by approximately 6%; missing immunizations were explained as failure to bill (43%), miscoding (27%), migration (20%), or no immunization (10%).

TABLE 1—Manitoba Immunization Monitoring System, Provincial Schedule of Routinely Recommended Immunizations, Acceptable Immunization Alternatives, and Tariff Codes

Tariff Code and Recommended Vaccine	Age	Tariff Code and Acceptable Alternative Vaccine
8601 DPT	2 mo	8641 DT or 8921 DPTP
8602 DTP	4 mo	8642 DT or 8922 DPTP
8603 DTP	6 mo	8643 DT or 8923 DPTP
8609 DTP	18 mo	8649 DT or 8929 DPTP
8509 DTP	5 y	8649 DT or 8929 DPTP
8659 Td	14 y	8609 DT or 8649 DT or 8929 DPTP
8611 OPV	2 mo	8921 DPTP or 8931 IPV
8612 OPV	4 mo	8922 DPTP or 8932 IPV
8613 OPV[a]	6 mo	8923 DPTP or 8933 IPV
8619 OPV	18 mo	8613 OPV or 8929 DPTP or 8939 IPV
8619 OPV	5 y	8929 DPTP or 8939 IPV
Hib[b]	2 mo	
Hib[b]	4 mo	
Hib[b]	6 mo	
Hib[b]	18 mo	
8670 MMR	12 mo	8621 measles
8661 rubella	12 mo	8670 MMR if given at or after 1 y of age

Note. DPT = diphtheria, pertussis, and tetanus vaccine; DT = diphtheria and tetanus toxoid; DPTP = diphtheria, pertussis, tetanus, and polio vaccine; Td = tetanus and diphtheria toxoid, "adult type"; OPV = oral polio vaccine; IPV = inactivated polio vaccine; Hib = *Hemophilus* b conjugate vaccine; MMR = measles, mumps, and rubella vaccine. The tariff code identifies the vaccine given by its generic type; for vaccines given in series, the last two digits identify the sequence. Physician billing claims use identical codes to represent immunization services.

[a]8613 OPV at 6 months of age is no longer recommended.

[b]Hib vaccine was not routinely recommended until 1992. Hib conjugate vaccine given in the same syringe with DTP: tariff codes 8781, 8782, 8783, 8789. All other Hib vaccines and Hib conjugate vaccine alone: tariff codes 8901, 8902, 8903, 8909.

TABLE 2—1989 Birth Cohort: Proportion with Immunization Schedule Complete, by Indian Status, Enrollment Status, and Place of Residence

	Infancy Schedule Recorded as Complete by First Birthday, % (No.)			
	Outside Winnipeg	Winnipeg		Total
		Inner City	Suburbs	
Non-Indian

[a]Recorded rates underestimate actual immunization rates because of migration.

[b]Recorded rates underestimate actual immunization rates because the federal health department did not fully participate in the Manitoba Immunization Monitoring System.

Population-Based Immunization Rates

System records of the total population of children born in 1989 and enrolled with the provincial Manitoba health plan in their first year of life (n = 18 048) were examined. Subgroups were defined by Indian status, enrollment status, and place of residence at the time of the initial Manitoba immunization. Recorded rates of completion of the recommended immunization schedule (three diphtheria–pertussis–tetanous immunizations and two oral polio vaccine immunizations, or appropriate alternatives [Table 1]) by the first birthday were calculated.

Results

For the total cohort, the recorded rate of schedule completion by the first birthday was 79%. Among children continuously enrolled during their first year of life, the completion rates were 91% for non-Indians (n = 14 853) and 45% for Indians (n = 1159) (Table 2). Recorded rates for children whose first-year enrollment was interrupted by migration (n = 1119) or by death (n = 119) were 40% and 20% for non-Indians and Indians, respectively.

The vast majority of children were continuously enrolled, the proportions being somewhat lower in Winnipeg's inner city (92%) than elsewhere (95%). The lowest completion rates recorded among continuously enrolled children were for non-Indians living in inner Winnipeg (87%) and for Indians living outside Winnipeg (39%).

Discussion

Like the Manitoba Immunization Monitoring System, computerized systems in use elsewhere measure the cumulative percentage of immunizations completed by certain ages in specified birth cohorts and calculate percentages of children up to date for recommended immunizations.[1,2] The Manitoba system, however, allows a closer look at the data; for example, calculation of the percentage of children receiving all scheduled immunizations within 30 days of the recommended age provides a measure of the proportion age-appropriately immunized.[3]

In addition to supplying measures of the quality of vaccination services, the system permits the definition of population subgroups by demographic characteristics and the calculation of rates by indicators (place of residence, Indian and enrollment status) of known influences on uptake: level of urbanization, access to service, and mobility.[4–7] Subgroups recording low coverage can be targeted and members tracked and offered immunization. Most children born in 1989 were up to date with recommendations by 1 year of age, regardless of area of residence. The low rates recorded among Indian children at least partially reflect jurisdiction-specific delays in data entry; manually recorded data from the federal health department suggest that coverage levels among Indian children are high. The effects of the rates recorded among Indians and migrants on overall rates are quantifiable and highlight the extent to which changes in the denominator influence reported coverage levels and limit comparisons between jurisdictions.[1,3]

The Manitoba Immunization Monitoring System is highly effective, relatively simple in design, and flexible to the needs of managers and users. It should be of interest to jurisdictions providing coverage of enrolled populations, such as American health maintenance organizations and other Canadian provinces. □

Acknowledgments

Patient Adherence to Guidelines for Diabetes Eye Care: Results from the Diabetic Eye Disease Follow-Up Study

Julie C. Will, PhD, MPH, Robert R. German, MPH, Earl Schurman, Sharon Michael, RN, MS, Donna M. Kurth, and Larry Deeb, MD

ABSTRACT

Early detection and treatment of diabetic eye disease can prevent blindness, yet many persons with diabetes lack regular eye care. This study followed 569 people with diabetes participating in blindness prevention programs during 1985 through 1987; it was found that 35% of subjects received dilated eye examinations before entering the programs, in comparison with 60% afterward. About 85% of participants referred for proliferative retinopathy treatment began such treatment, and, of these, 85% completed treatment. A lack of knowledge about the disease and limited finances were primary reasons for nonadherence. To improve the effectiveness of prevention programs, eye care providers and program staff must strive to eliminate these educational and financial barriers. (*Am J Public Health.* 1994;84: 1669–1671)

Introduction

Diabetes is a leading cause of blindness in US adults.[1] Laser therapy applied to advanced diabetic proliferative retinopathy reduces the risk of severe vision loss by 50% or more.[2] Blindness prevention guidelines emphasize early detection of diabetic eye disease.[3–9] Recent studies indicate, however, that about a third of people with diabetes have never had ophthalmologic examinations and that more than half of these individuals have eye disease.[10,11] To improve the eye care of diabetic persons and prevent blindness, the Centers for Disease Control and Prevention (CDC) has worked with 27 state health departments to develop and implement blindness prevention programs.* Program staff have identified persons with diabetes who have not had a dilated eye examination within the previous year, have examined them to detect eye disease, and have educated them about the need for annual examinations and adherence to treatment recommendations. Here, we summarize the findings of the Diabetic Eye Disease Follow-up Study, which was designed to evaluate and improve the effectiveness of these state programs.

Methods

In 1988, the CDC requested proposals for participation in the Diabetic Eye Disease Follow-up Study from among the 10 state blindness prevention programs that had operated in the United States prior to 1987. Proposals were accepted from programs that had served at least 50 persons with diabetes before October 1, 1986, and were able to track these individuals. Four programs were eligible, and all were approved for funding by a CDC technical review committee. The study was approved by a CDC institutional review board.

Between 1988 and 1990, the study assessed the programs described in the Appendix. Between 1985 and 1987, 2106 people participated in the programs. Of these, we followed 569 individuals from a probability sample of Whites, Blacks, and Hispanics and a census of people from other racial/ethnic groups for 2 to 5 years. Nonparticipants were not identified or followed.

To select the sample, we employed stratified random sampling and used program records to define strata based on geographic location, urgency of treatment, and racial/ethnic group. Program participants in each location (i.e., Minnesota, Florida, Maryland, the eastern plains of Colorado, and inner-city Denver) were categorized into four groups by urgency of recommended treatment as defined by the clinical judgment of individual eye care specialists. Participants diagnosed with diabetic eye disease that required immediate treatment constituted the first group. Participants with diabetic eye disease that required reexamination in less than 1 year but not immediately composed the second group. Participants without diabetic eye disease who were

*CDC now works with 40 state and territorial health departments. Rather than provide eye care services, current programs concentrate on core public health functions (e.g., surveillance, quality assurance, access).

TABLE 1—Racial/Ethnic Characteristics of the US Diabetic Population, Program Participants, Individuals Selected for Study, Study Participants, and Subjects with Complete Medical Records

	White, %	Black, %	Hispanic, %	Other, %
US diabetic population (n = 4 778 000)	70.8	19.4	7.3	2.5
Program participants (n = 2106)	65.1	22.5	10.8	1.6[a]
Selected sample (n = 569)[b]	61.0	23.9	11.1	4.0
Completed interview (n = 414)	59.4	25.6	12.6	2.4
Complete medical record (n = 336)[c]	62.8	23.8	11.6	1.8

[a]Determined by use of program records. When interview data were used to determine racial/ethnic category, 10 of these individuals were later reassigned to the Black, White, or Hispanic category (the selected sample reflects this reassignment).
[b]One person was dropped from the sample because we were unable to definitively classify this individual by racial/ethnic category.
[c]The population of persons with diabetes who received a diagnostic examination and who had information recorded on the medical record abstraction form. These data were used to calculate treatment initiation and completion rates.

recommended for routine reexamination in 1 year constituted the third group. Finally, the fourth group included participants not classifiable by urgency of treatment. Individuals within each geographic area and group were then further stratified by racial/ethnic status. Within each area, all persons in the first group were selected for study (n = 172) to allow us to calculate treatment initiation and completion rates. The other groups were sampled to match the proportion of Blacks, Whites, and Hispanics in the first group.

Diabetic Eye Disease Follow-up Study investigators sent information to potential respondents, explaining the study's purpose and asking for permission to review medical records. Within 2 weeks, interviewers called subjects to request permission for a telephone interview. Interviewers made five attempts to contact each subject by telephone, made up to three visits to the subject's home, and, as a final attempt, sent the subject a questionnaire by mail. The 62-item, 20-minute questionnaire covered topics such as eye care history, knowledge, and barriers. Program eye evaluation records were then abstracted. If a medical release form was signed, the abstractor reviewed records from the subject's most recent eye care visit. The abstractor recorded the results of recommended treatment and reasons for not initiating treatment.

We employed various quality control procedures and used SUDAAN software to calculate proportions and standard errors and to conduct logistic regression analysis.[12] We used statistical weighting (corrected for nonresponse/lost to follow-up) to permit extrapolation to the total population of program participants.

Results

Four hundred forty-nine (79%) of the 569 subjects were contacted (complete medical records were obtained for 336 individuals, and interviews were completed for 414). One hundred twenty people (21%) were not contacted (74 had died, and 46 could not be reached).

Participants were more likely than the general diabetic population to be female, to use insulin, to be overweight, and to be financially disadvantaged (data not shown). They were also more likely to be Black or Hispanic (Table 1). The racial/ethnic status of persons who completed the interview or had complete medical records was not substantially different from that of all program participants.

We first determined the proportion of program participants initiating and completing treatment. As a result of program participation, 3% of persons were diagnosed with proliferative retinopathy, of whom 70% were referred for treatment. Treatment was initiated by 85% of the subjects referred, and, of these individuals, 85% completed the treatment. Of participants diagnosed with nonproliferative retinopathy, 5% were referred for treatment. Of the subjects referred, 48% initiated treatment, and of these individuals, 82% completed treatment.

Of the 74 individuals referred for treatment for proliferative or nonproliferative retinopathy, 25 (34%) did not initiate treatment within 1 year. Eye care records revealed that 12 (49%) of the 25 who did not initiate treatment were under the care of a doctor and were awaiting treatment; 6 (24%) persons indicated that they did not want treatment, and 1 (4%) had died. Reasons for not initiating treatment were not given in records for the remaining 6 subjects.

Second, we assessed the proportion of subjects who received annual examinations after joining the program. Sixty percent of interviewed participants reported receiving an annual examination during the year preceding the interview. Logistic regression analysis showed that proliferative and preproliferative retinopathy detected during the program's diagnostic examination strongly predicted later adherence to annual examination (odds ratio [OR] = 5.7, 95% confidence interval [CI] = 3.7, 8.8, for proliferative retinopathy; OR = 12.4, 95% CI = 7.0, 22.0, for preproliferative retinopathy). Also, the more recently patients participated in a blindness prevention program, the more likely they were to have annual examinations ($P = .002$).

Those who had not received an annual examination offered numerous explanations. The two most common reasons—given by approximately 60% of the respondents—were that they could not pay for an examination and that they had no visual symptoms.

Discussion

Evidence suggests that people who have never received eye care have difficulty adhering to eye care recommendations.[13] Only 35% of our subjects had received a dilated eye examination during the year prior to enrolling in a blindness prevention program. Despite this, 85% of program participants recommended for proliferative retinopathy treatment initiated and completed treatment. Furthermore, they continued receiving eye examinations. Two to 5 years after joining a program, 60% of participants reported having received an eye examination within the previous year. Indeed, diagnosis of retinopathy during program participation and recency of program participation strongly predict adherence to annual eye examination.

Given the effectiveness of retinopathy treatment, nonadherence to treatment recommendations signals a seriously

flawed system. Programs can improve this system by identifying people who do not initiate or complete retinopathy treatment and the reasons why they do not. Eye care providers should aggressively pursue and record the reasons for nonadherence and work with prevention program personnel to eliminate treatment barriers. Program personnel should consider establishing an annual examination reminder system to advise people with diabetes that retinopathy is often a silent disease and that annual examinations are important even when no visual symptoms are evident. Moreover, reminders should offer people information about low-cost services and other strategies to overcome financial barriers. □

APPENDIX—Descriptions of the Four Blindness Prevention Programs Used in the Study

Maryland

The Maryland program employed a two-person team from the Johns Hopkins Diabetes Center to conduct eye disease screenings at 14 sites throughout a wide geographic area. Free screenings were conducted at community health centers, hospitals, local health departments, and local American Diabetes Association chapters. Those who had not received a dilated eye examination during the previous year were asked to identify themselves by responding to newspaper and public service announcements and to promotions at local diabetes education classes and American Diabetes Association chapter meetings. Identified persons were then recruited for nonmydriatic fundus photography of each eye, visual acuity testing, tonometry, blood pressure measurement, and eye care education. Seven hundred seventy-three persons with diabetes participated between 1985 and 1987. The photographs were read by a retinal specialist at Johns Hopkins University. Patients were referred to an ophthalmologist if proliferative retinopathy was detected. All other patients were urged to seek diagnostic examinations.

Florida

People with diabetes were examined for eye disease at two Pinellas County public health units located in St. Petersburg and Clearwater. This program was available to public health clinic clients with diabetes who had not received a diagnostic eye examination within 12 months prior to the screening examination. Local print, radio, and television media participated in announcing the availability of screening services for public health clients. Five hundred seven persons with diabetes participated between 1985 and 1987. The examination included visual acuity testing, intraocular pressure measurements, nonmydriatic retinal photographs of both eyes, and eye care education. Retinal photographs were sent to a university-based school of ophthalmology for evaluation. Depending on ophthalmologists' judgments of the severity of disease, patients were referred either for a confirmatory diagnostic examination or for routine follow-up within 1 year.

Minnesota

An epidemiologic study in Marshall enumerated all individuals with physician-defined diabetes who used the local medical care system (n = 533). Those who reported never having had an ophthalmologic examination (n = 172) were referred for a free eye examination at a local ophthalmologist's office. One hundred forty-five persons (85%) received the examination, which included visual acuity testing, tonometry, dilated funduscopic examinations, and mydriatic fundus photography. If proliferative retinopathy with high-risk characteristics was detected by the ophthalmologist, patients were given immediate treatment. Those with less serious eye disease were recommended for follow-up. Patients were also given eye care education at a community-based education program located at the same health care center as the ophthalmologist's office.

Colorado

The Colorado program targeted residents of inner-city Denver and the rural eastern plains. The inner-city residents generally have low incomes and traditionally do not use preventive health practices for diabetes control. Diabetes status was determined by reviewing medical and billing records of a major inner-city medical facility. The medical charts of all persons with diabetes were then identified by affixing brightly colored stickers to the patient's problem list. Health care providers were asked to use these charts to identify persons with diabetes and to refer those who had not had an eye examination during the past year to the medical facility's eye clinic. Residents of the eastern plains are dispersed throughout a large geographic area that has limited ophthalmologic services. These program participants were recruited through public announcements and by asking primary care physicians and health facilities to refer persons with diabetes to the program. Program publicity included announcements via radio and newspapers, hospitals, and pharmacies. Announcements emphasized that persons with diabetes who had not had a dilated eye examination during the past year were eligible for the program. All recruited persons were examined by an ophthalmologist who was in private practice or was temporarily located in a special clinic. Six hundred eighty-five persons with diabetes participated in the program between 1985 and 1987.

The Risk of Hospitalization for Ischemic Heart Disease among Asian Americans in Northern California

Arthur L. Klatsky, MD, Irene Tekawa, MA, Mary Anne Armstrong, MA, and Stephen Sidney, MD

ABSTRACT

To supplement sparse data about ischemic heart disease in Asian Americans, hospitalization risk was prospectively examined in a group of Asian Americans living in Northern California. Analyses used Cox models with ischemic heart disease risk traits as covariables. With Whites as the referent category, relative risks by ethnic group were as follows: Chinese, 0.6 ($P = .001$); Japanese, 1.0 ($P = .97$); Filipinos, 1.0 ($P = .95$); South Asians, 3.7 ($P < .001$); other Asian Americans, 0.8 ($P = .55$). Thus, unexplained differences in ischemic heart disease risk exist among Asian-American ethnic groups, with Chinese Americans at lowest risk and persons of South Asian origin at highest risk. (*Am J Public Health.* 1994;84:1672–1675)

Introduction

Considering the recent rapid increase in numbers of Asian Americans, data about health risks in this group remain scanty.[1–3] Prospective data about ischemic heart disease incidence are limited to epidemiological surveys among Japanese Americans residing in the United States.[4–6] These surveys show more ischemic heart disease among Japanese Americans than among Japanese living in Japan, a finding attributed to life-style changes. Studies of ischemic heart disease risk factors among Chinese Americans suggest that their risk is probably low.[7,8] Two reports suggest a high prevalence of hypertension among Filipino Americans.[9,10] Reports of a high ischemic heart disease prevalence among overseas Asian Indians in various countries have appeared.[11–18] To address the clear need for more data about ischemic heart disease in Asian-American ethnic groups, we here report prospective data about hospitalization for this condition.

Methods

We used data from 13 245 Asian Americans who voluntarily took health examinations offered by a Northern California prepaid health care program from 1978 through 1985. The self-administered questionnaire included the question "What is your race?" (Options: Black, White, Oriental [Asian], Latin, Mixed, and Other.) Subheadings under Oriental (Asian) were Chinese (n = 6064), Japanese (n = 1718), Filipino (n = 4283), and Other Asian (n = 1180). A separate query about birthplace yielded 274 South Asians ("Other Asians" born in India or Pakistan); the remainder are called "Other Asians" in this paper. The study population and examination procedure, which included health measurements and blood tests, have been described elsewhere.[8,19] Hospitalizations for ischemic heart disease were identified primarily by hospital discharge codes 410 through 414 (*International Classification of Diseases*, Ninth Revision[20]) in records of hospitals used by the health care program.

The subjects were followed from the date of first examination until December 1989, termination of health plan membership, or first hospitalization for ischemic heart disease (whichever was earliest). This procedure yielded 207 persons with such hospitalizations (99 for acute myocardial infarction and 108 for other ischemic heart disease diagnoses). Cox proportional hazards models were used for analyses, with age, sex, smoking (never smoker, ex-smoker, <1 pack/day, ≥1 pack/day), body mass index, marital status (married, never married, formerly married), education (no college, some college, college graduate), and alcohol intake (never drinker, ex-drinker, <1 drink/day, ≥1 drink/day) as covariates. Systolic blood pressure, total serum cholesterol, and random blood glucose were also included in some models. The use of these two models enabled study of the role of these established ischemic heart disease risk factors in the results. Comparisons were made between each Asian-American group and Whites (using a 10% random sample of Whites as the referent; n = 7206, of which 212 had been hospitalized for ischemic heart disease) and between the Asian-American groups themselves (using the largest subset, Chinese, as the referent). The results are expressed as relative risks (RRs) for hospitalization for ischemic heart disease.

Of the 13 245 Asian-American subjects, 33.1% terminated membership in the health care program by December 1989. By ethnic group, the percentages were Chinese, 33.8%; Japanese, 33.8%; Filipinos, 28.3%; South Asians, 44.5%; other Asians, 46.4%; Whites, 35.9%.

The authors are with the Division of Research, Kaiser Permanente Medical Care Program, Oakland, Calif; Dr Klatsky is also with the Division of Cardiology.

Ischemic heart disease risk "yes,"[c] %	26.5	30.4	40.2	29.9	31.1	32.8
Mean follow-up, y	7.3	7.4	7.4	6.4	6.2	7.1

[a]All persons in this subset stated that they were Asian and were born in India or Pakistan.
[b]Weight in kilograms divided by height in meters squared.
[c]See Methods for definition.

We attempted to identify persons who were free of or at low risk for ischemic heart disease. A person was considered at risk if he or she answered "yes" to any of 12 health history questions suggesting lifetime history of ischemic heart disease, symptoms of ischemic heart disease, or risk factors for ischemic heart disease (hypertension, diabetes, hypercholesterolemia).

Results

Tables 1 and 2 present descriptive data and age-adjusted hospitalization rates for the Asian-American groups. Age-specific rates for Chinese men were roughly half those of Whites; rates for South Asian men were two to four times those of Whites. For example, rates per 1000 person-years among men aged 45 through 59 years were 5.6 for Whites, 2.9 for Chinese, and 21.9 for South Asians; among men aged 60 years or older, rates were 16.0 for Whites, 8.3 for Chinese, and 34.7 for South Asians.

The risk of hospitalization, adjusted for risk factors, was similarly lower in Chinese Americans and higher in South Asians than in Whites (Table 3). Separate analyses by sex showed the following statistically significant relative risks (with 95% confidence intervals [CIs]): Chinese vs White men, 0.6 (0.4, 0.8); South Asian vs White men, 4.4 (2.1, 8.7); Filipino vs White women, 2.3 (1.2, 4.2). Other comparisons by sex of Asian subsets vs Whites were not significant; there were no cases of ischemic heart disease among South Asian women and therefore no risk ratios. The covariates showed expected relationships to ischemic heart disease risk. In the model with Whites as the referent, the following relative risks were found: age, 1.8 per 10 years ($P < .001$); male sex, 3.5

TABLE 2—Age-Adjusted Rates of Hospitalization[a] for Ischemic Heart Disease in Asian Americans and Whites, by Sex

TABLE 4—Adjusted Relative Risk of Hospitalization[a] for Ischemic Heart Disease: Asian-American Ethnic Groups vs Chinese Americans

Ethnicity	Relative Risk	95% Confidence Interval	P
Chinese (referent)	1.0	...	...
Japanese	1.8	1.2, 2.7	.006
Filipino	1.9	1.3, 2.7	<.001
South Asian	6.6	3.2, 13.6	<.001
Other Asian	1.3	0.6, 3.1	.49

[a]Computed by Cox proportional hazards models controlled for age, sex, smoking, body mass index, marital status, education, and alcohol intake.

($P < .001$); body mass index, 1.1 per unit (kg/m^2) ($P < .001$); current smoking of 1 or more packs per day (vs never smoking), 1.8 ($P = .002$); current alcohol intake of 1 or more drinks per day (vs never drinking), 0.4 ($P < .001$); systolic blood pressure, 1.1 per 10 mm Hg ($P < .001$); total cholesterol, 1.1 per 0.25 mmol/L ($P < .001$); glucose, 1.03 per 0.5 mmol/L ($P < .001$). Compared with the Chinese, the Japanese, Filipino, and South Asian groups were all at higher risk, with a striking relative risk for South Asians vs Chinese (Table 4). The confidence intervals were wide for the comparisons of South Asians vs Whites and South Asians vs Chinese because of small numbers, but the P values for both comparisons were <.001. These results were little affected by inclusion of cholesterol, blood pressure, and glucose in the analyses. Addition of the ischemic heart disease risk variable (for "yes" vs not "yes," RR = 2.6, 95% CI = 2.1, 3.4) to the multivariate model resulted in only minor changes in relative risk estimates: for example, for Chinese vs Whites, RR = 0.6 either way; for South Asians vs Whites, RR = 3.7 with no control for ischemic heart disease risk and 3.8 with control for ischemic heart disease risk.

Discussion

To our knowledge, this is the first report of differences in ischemic heart disease risk that includes data for most of the major Asian-American ethnic groups living in the United States. Hospitalization represents only part of the clinical ischemic heart disease spectrum. This could be an important limitation if there are ethnic differences in the decision to hospitalize a patient who has experienced an ischemic heart disease event. We believe this is unlikely because of probable, similarly high identification of ischemic heart disease events among ethnic groups in this study sample. All subjects were sufficiently health conscious to take a health examination. In this study the ischemic heart disease risk of Japanese and Filipino Americans was similar to that of Whites. The data for Japanese Americans are consistent with extrapolation of the apparent effects of acculturation on ischemic heart disease risk in this group seen in previous studies.[4–6] Nearly 80% of Japanese Americans in this study population were US-born, and their traits were similar to those of US Whites.[8,19] Although 90% of the Filipino Americans in this study were born in the Philippines, the high prevalence of hypertension[9,10] and relatively high levels of ischemic heart disease risk factors in this group[8] seem sufficient to explain their ischemic heart disease risk. Efforts toward ischemic heart disease risk factor control in these groups should probably parallel those among US Whites and Blacks.

A lower ischemic heart disease risk in overseas Chinese has been reported in a multiethnic Singaporean population, without explanation.[13] A prediction of lower risk in Chinese Americans in this study population[8] was based on its lower prevalence of established ischemic heart disease risk factors. Our finding of lower risk for the Chinese Americans in the present study, independent of the controlled risk factors, does not rule out this explanation. Measurement of traits at a single point in time does not control for lifelong risk. Uncontrolled factors (e.g., high-density lipoprotein [HDL] cholesterol, physical activity, psychological traits) may be involved. We hope that others will explore these aspects. With further follow-up, larger numbers of subjects with ischemic heart disease will enable separate study of Chinese Americans born in China, Taiwan, Hong Kong, Hawaii, and the mainland United States and may provide further clues about ischemic heart disease risk in this ethnic group.

Our data show that Asian Americans of South Asian origin are at very high risk for ischemic heart disease. Although the number of cases is small (with resultant wide confidence intervals), the validity of the finding is strongly supported by reports from other countries.[10–18] Consistency in diverse environments suggests that an intrinsic genetic or cultural trait is involved. An explanation in terms of established risk factors is not yet clear. There seem to be large disparities in incidence of ischemic heart disease in various portions of India.[18] Others have considered the most promising explanatory hypothesis to be high prevalence of diabetes mellitus, central obesity, and insulin resistance.[12,15–18] Our data, controlled for blood glucose and body mass index, do not support this hypothesis, but we unfortunately have no data about HDL cholesterol, apolipoproteins, lipoprotein(a), or other possible lipoprotein factors. Our control for body mass index is also an inadequate test of this hypothesis, in the absence of data about skinfold thickness or waist-to-hip ratios. It is apparent that further research about the epidemic of ischemic heart disease in overseas South Asians is an urgent public health need. Whatever the explanation may prove to be, aggressive evaluation and modification of risk for ischemic heart disease in South Asian Americans seems appropriate. □

The Effects of Denturism: New Zealand Dentists' Response to Competition

Nancy Joy Devlin, PhD

ABSTRACT

The New Zealand Dental Act of 1988 allowed clinical dental technicians to deal directly with the public in fitting and supplying dentures. This study tested the hypothesis that dentists responded to competition from dental technicians by lowering their fees. The results indicate that there was no significant change in the fees charged by dentists for dentures. The apparent failure of deregulation to produce the expected outcome could be due to the competitive pressure imposed by dental technicians practicing illegally prior to 1988, to consumers' lack of information, or to barriers to "consumer search" imposed by the act itself. (*Am J Public Health.* 1994;84:1675–1677)

Introduction

Adult dental care in New Zealand is provided mainly by self-employed, privately practicing dentists and is financed predominantly by out-of-pocket payments by consumers; few state subsidies exist and coverage by insurance plans is minimal.[1] In 1988 the New Zealand government changed the legal provisions regarding the practice of dentistry.[2] Regulations that were viewed as conferring "monopoly rights" on dentists were removed, allowing clinical dental technicians ("denturists") to deal directly with the public in supplying and fitting complete and partial dentures ("denturism").

New Zealand legislators expected deregulation to lead to an increase in the supply of dental services, which would, all other relevant variables remaining unchanged, lead to a decrease in the price of these services. It seems plausible to assume that these effects would be evident 4 years after the change in competitive environment. Owing to the use of "grandfather rights" in the registration of previously practicing dental technicians as "clinical dental technicians," the increase in the legal supply of dental services took place within a relatively short time frame. The number of clinical dental technicians registered under the Dental Act was 129 in 1993 (around 4 per 100 000 population); the number of dentists issued annual practicing certificates in that year was approximately 1300. The introduction of the Dental Act increased the total dental work force (those able to deal directly with the public) by around 10%, although the increase in the effective supply of denture services would be larger than 10% because dentists spend a relatively small proportion of their chairside time on dentures (6% in 1988). Fee data from annual surveys of dental practices were used to test the following hypotheses:

1. That the fees charged by dentists for full and partial dentures would increase at a different rate from the fees charged for other services after 1988. As competition from nondentists principally affected the market for dentures, there should be an observable difference between dentists' pricing of dentures and their pricing of other services.

2. That the spread of fees charged by dentists for dentures would narrow in the

TABLE 1—Actual and Predicted[a] Fees and Fee Indices for New Zealand Dental Services

	Actual				Predicted, 1992	Difference between Actual and Predicted, %	95% Confidence Interval	r^2
	1978	1983	1988	1992				
Fees[b]								
Examination and simple prophylaxis	$8	$16	$30	$39	$38	+2.6	$34, $44	.974
Single extraction, local anesthetic	$12	$24	$46	$60	$57	+5.3	$70, $50	.962
Amalgam filling, one surface	$7	$15	$30	$40	$37	+8.1	$45, $32	.961
Crown (bonded)	$126	$232	$399	$495	$494	+0.2	$577, $452	.975
Full (upper and lower) dentures	$224	$383	$673	$809	$817	−1.0	$970, $729	.965
Acrylic partial (one tooth)	$62	$117	$203	$259	$262	−1.2	$333, $212	.929
Fee indices[c]								
Denture price index[d]	100	180	314	438	394	+10.0	478, 342	.956
Other dental services[e] price index	100	199	376	551	467	+15.2	558, 431	.968
Relative fee index[f]	100	90	84	80	80	0.0	100, 58	.330

[a]Predicted fees and fee indices for 1992 were estimated from a least squares linear regression of fee data for the years 1978 through 1988.
[b]All fees shown are in current dollar terms (i.e., they are not inflation adjusted) and exclude goods and services taxes.
[c]In each case, the index base is 100 in 1978.
[d]Denture services = partial acrylic, one tooth; complete upper and lower dentures.
[e]Other dental services = examination and simple prophylaxis; single extraction, local anesthetic; amalgam filling, one surface; bonded crown.
[f]Relative fee index = (denture price index/other dental services price index) × 100.

post-1988 period because a wide range of fees charged for the same service is incompatible with the functioning of a competitive market.[3]

Methods

Data on the fees charged by New Zealand dentists are available for 1978, 1981, and annually from 1983 through 1985 and 1987 through 1992, providing a time series spanning 10 years before and 4 years after the 1988 New Zealand Dental Act. These surveys, which are conducted by the New Zealand Dental Association, sample more than 30% of all privately practicing dentists in each year and provide data on the "normal, average, uncomplicated fee" charged by each dentist for a range of items. For the purposes of this study, six fee items were selected: two for dentures (full and partial) and four for other services frequently performed by dentists.

Regression analysis of dentists' fees for the years preceding the Dental Act (1978 through 1988) was used to estimate a least-squares linear trend line, from which expected charges for each item in the period 1989 through 1992 were predicted. These predicted fees were compared with the actual fees charged.

Price indices (with a base of 100 in 1978) were constructed for two groups of dental services—dentures and other dental services—and a relative fee index (RFI) was calculated as follows:

$$\text{RFI} = \frac{\text{Denture Price Index}}{\text{Other Dental Services Index}} \times 100$$

Linear regression of all three indices for the period 1978 through 1988 was used to predict index values for 1989 through 1992, which were compared with actual index values.

Results

Table 1 shows the actual fees charged in selected years and the 1992 fees predicted from pre–Dental Act data. For both full and partial dentures, the actual fees charged in 1992 were lower than predicted; for all other items, 1992 fees were higher than predicted.

Although the direction of these changes appears to support the initial hypothesis, the magnitude of the changes is small. For all treatment items, the actual fee charged in 1992 falls easily within the 95% confidence interval for the 1992 prediction, suggesting that fee charging has not changed substantially for any of these items as a result of the new legislation.

In the post-1988 period, the price index for both dentures and other dental services increased more quickly than predicted (Table 1). The predicted 1992 value of the relative fee index coincided exactly with the actual 1992 value of the index (although the regression r^2 of .33 suggests that no significant linear trend could be fitted). The relative fee index indicates that there was a tendency for denture prices to rise more slowly than other dental prices before 1988, and that this trend continued thereafter. The Dental Act appears to have had no significant influence on the denture price index or the relationship between denture prices and other dental treatment prices.

Table 2 shows the coefficient of variation of fees for each treatment item. There appears to have been little reduction in the dispersion of fees charged for dentures as a result of the Dental Act. The fees charged for full dentures between 1989 and 1992 show the least variability of all treatment items; however, this was also true of the pre–Dental Act period.

Discussion

There are a number of possible explanations for the apparent lack of market response to the Dental Act.

Evidence that the illegal practice of dental technicians was widespread prior to 1988[4] suggests that the main achievement of deregulation may have been to sanction this activity rather than to pro-

TABLE 2—Variability in Fees Charged by New Zealand Dentists, as Measured by the Coefficient of Variation in Fees Charged for Selected Dental Services in 1988 and 1992

Service	Coefficient of Variation[a] 1988	1992
Examination and simple prophylaxis	26	25
Single extraction, local anesthetic	22	22
Amalgam filling, one surface	27	23
Crown (bonded)	19	13
Full (upper and lower) dentures	17	19
Acrylic partial (one tooth)	28	27

[a]Coefficient of variation = (standard deviation/mean) × 100. A high coefficient of variation indicates a greater degree of variability in fee charging between individual dentists.

mote more competition. This possibility is consistent with evidence that the fees charged for full dentures tended to increase less quickly than the fees for other dental services even before the Dental Act. It is also consistent with the finding that the indicator of fee dispersion for full dentures was lower than that for other dental services both before and after 1988.

Legalizing competition may have produced few additional gains because of consumers' lack of information. Whereas denturism has been introduced elsewhere as a consequence of strong consumer lobbying,[5,6] the New Zealand Dental Act was primarily the result of government initiatives. There was little public awareness of, or debate over, the legislation. Consumers' perceptions regarding the quality of care offered by dentists, relative to that offered by technicians, might also partly explain the finding that competition between these suppliers did not affect dentists' fees. Furthermore, advertising by dentists and technicians, although legal, is very low-key in comparison with advertising in the United States, where denturism has been demonstrated to result in lower prices.[7]

The act itself also imposes some barriers to "consumer search"; for example, denturists may fit partial dentures only for persons whose oral health is certified by a dentist.

At the time the Dental Act was introduced, technicians' fees were estimated to be, on average, 30% lower than those of dentists.[8] Dentists' response to the act suggests that these price differentials are likely to persist. □

Public Health Then and Now

The Medical Care Programs of the Farm Security Administration, 1932 through 1947: A Rehearsal for National Health Insurance?

Michael R. Grey, MD, MPH

ABSTRACT

At a time of renewed interest in universal health insurance, an examination of earlier periods when society grappled with the link between socioeconomic status and health is fruitful. Between 1935 and 1947, the federal government sponsored a comprehensive medical care program for low-income farmers, sharecroppers, and migrant workers under the auspices of the Farm Security Administration (FSA). Despite the strong opposition of the American Medical Association, humanitarian and economic concerns at the local level often promoted physicians' participation in the program's group prepayment plans. Many FSA leaders clearly saw the program as a model upon which national health insurance might advance. However, in the wake of World War II, the FSA program declined as physicians' income improved, the rural population declined, and traditional ideological objections to federal intervention in medical care resurfaced. The FSA experience illuminates the complex ideological, economic, and humanitarian motivations of American physicians in the face of health care reform. (*Am J Public Health.* 1994;84: 1678–1687)

Introduction

From 1935 to 1947, the federal government sponsored an extensive civilian medical care program under the aegis of the US Department of Agriculture's Farm Security Administration (FSA). The FSA's mission—to rehabilitate low-income farmers, sharecroppers, and migrant workers—led it to develop a comprehensive medical care program described by the *Saturday Evening Post* as a "gigantic rehearsal for health insurance."[1] At the program's peak, more than 650 000 poor farmers and a million migrants were enrolled in medical care cooperatives or farm labor clinics in a third of all rural counties (Figure 1). Although the New Deal has been richly mined by historians, remarkably little has been written about this "gigantic rehearsal" in the nearly half-century since it ended.[2–4]

Until the passage of Medicare and Medicaid, the FSA program was the largest government-sponsored program dedicated to providing medical care for a specified civilian group. The FSA's success owes much to strategies the agency adopted to promote its medical program among skeptical physicians. These strategies are relevant guidelines as our nation again confronts the issue of national health security. Eager to avoid confrontation with both local physicians and organized medicine, the FSA emphasized free choice of physician and voluntary participation. Its decentralized approach promoted local autonomy and gave physicians substantial but not absolute control over the operation of the medical care plans. Certainly, philanthropies, unions, physicians, and private industry sponsored various prepaid health care plans throughout this period and even earlier. However, the public/private character, extensive enrollment, comprehensive coverage provisions, and preventive orientation of the FSA program gives it a historical import that exceeds that of earlier or parallel health care delivery programs.

Throughout most of this period, the American Medical Association vehemently opposed federal involvement in medical care delivery. In spite of this opposition, physician support of the FSA plans at the grassroots level was substantial and was driven by humanitarian and economic concerns. While physicians saw the program as a temporary federal effort to provide medical care to an indigent group, the agency itself pursued a broader public health agenda. The FSA's extensive public and preventive health efforts and its systematic use of public health nurses, nutritionists, and US Public Health Service medical officers belie the public posture assumed by the agency. Over time, the FSA's multifaceted rural health programs and its eventual alliance with reformers favoring national health insurance made physicians increasingly uncomfortable. This discomfort coincided with physicians' improving incomes and the easing of the economic pressures on them in the years leading up to World War II. Growing congressional opposition to New Deal social legislation, the divisive debate over national health insurance, and concerted opposition to the FSA by conservative farm groups only added to the agency's woes. In sharp contrast, other

privately funded voluntary group prepayment plans (e.g., Kaiser Permanente, Blue Cross, and physician service bureaus) were less vulnerable to attack and made steady gains in the postwar era.[5] In retrospect, however, the root cause of the FSA plans' eventual demise was an ideological conflict between the government and the medical profession.[6,7] For this reason, the history of the FSA medical care program illuminates the ideological, economic, and humanitarian motivations of American physicians in the face of health care reform.

Medicine and Health in the 1930s

American medicine, like much of society in the 1930s, was in transition. Solo practice and fee-for-service still dominated medical practice, and rural hospitals were few and often proprietary. However, the waning influence of general practitioners, the rising dominance of specialists, and centralization of care in hospitals were well under way by that time.[8] In 1932, the Committee on the Costs of Medical Care published its landmark report *Medical Care for the American People*, the most exhaustive and influential study of the state of American health and medicine that had ever been published. The committee found that poor communities experienced more sickness and received less care than more affluent communities. Medical resources, while plentiful, were not "distributed according to needs, but rather according to the real or supposed ability of patients to pay for services."[9] The numerical, income, and geographical imbalance between general practitioners and specialists led the committee to conclude that the nation needed far fewer specialists and far more general practitioners. Finally, the committee linked access and cost barriers as critical issues for underserved populations, setting the tone for virtually all health care reforms to the present day.[10] An obvious but often neglected fact is that the most nettlesome problems in our health care system antedated changes such as the explosion of medical technology, the acceleration of medical specialization, and the dominance of hospital-based care in the wake of World War II. The committee's 1932 report calling for an integrated system in which generalists provide the majority of acute and preventive services was prescient.

The Great Depression greatly exacerbated but did not create the problems highlighted by the Committee on the Costs of Medical Care. Unemployment soared to an unprecedented 25%, overwhelming private and local relief agencies. Lack of money forced many people to go without medical services, and a single serious illness was enough to plunge a large and steadily increasing percentage of American families into prolonged debt. "I have to treat many families," lamented one physician, "shutting my eyes to the fact that not one of my instructions can be carried out."[11] Physicians' net income plunged by 17%, and many rural physicians' incomes dropped below 50% of billings.[12] Other health care professionals were similarly affected.

The Great Depression devastated rural America. Mechanization and land consolidation, the nation's worst-ever drought, and blunt legislative efforts such as the Agricultural Adjustment Act conspired to create the largest internal migration in our history. Vast numbers of families left their farms buried in dust, loaded up their jalopies, and headed west (see photo on next page). The Department of Agriculture estimated that between 1 and 2 million of the estimated 10.5 million people employed in agriculture were migrants.[13]

The health conditions of rural citizens, which had been declining relative to those of urban Americans since the turn of the century, were also adversely affected. Rural areas had 80 physicians per 100 000 population, vs 171 per 100 000 in urban areas. In 1900, nearly 50% of medical school graduates practiced in rural areas; by 1931, fewer than 21% did so.[14] In metropolitan areas, 72% of births occurred in hospitals, infant mortality was 34.2 per 1000 live births, and immunizations averaged 89%. In contrast, only 14% of rural babies were born in hospitals, rural infant mortality was 43.3 per 1000 live births, and only 37% of rural children were immunized.[15] In New England there were 81 hospital beds per 100 000 population, while in the more rural South there were only 30 beds per 100 000. Ninety-four percent of all water supplies in the South, according to the 1940 census, were open; 66% of Southerners still used privies, and fewer than 12% had potable water within 50 feet. A third of the nation's 3070 counties had no public health unit; virtually all were rural.[16]

Health conditions among migrants were particularly abysmal. Outbreaks of infectious diseases such as typhoid, dysentery, and tuberculosis created vigilante movements that were sometimes led by local health departments. Wrote one county health officer, "One has to deal with a people whose cultural and environmental background is so bad that for a period of more than 300 years no advances have been made in living conditions among them."[17] Racism, xenophobia, and fear of contagion—powerful historical themes in society's response to

disease epidemics—led to the violent and systematic destruction of squatter camps or "Hoovervilles." To many people, disease and degraded mortality seemed equally contagious.[18]

Roosevelt quickly moved to promote massive federal intervention during the famous "100 days" of his presidency. Congress passed an omnibus relief measure creating the Federal Emergency Relief Administration (FERA) in March 1933. The FERA channeled direct federal relief through state emergency relief administrations and created a division devoted solely to rural relief and rehabilitation. The hallmarks of the FERA rural rehabilitation program—friendly supervision and easy credit—remained at the core of all subsequent efforts. The creation of the Works Progress Administration (WPA) and the Resettlement Administration in 1935 signaled a shift in federal policy away from direct monetary relief. The more well-known WPA concentrated on massive infrastructure projects and urban work relief. The Resettlement Administration assumed the rural rehabilitation prerogatives of the FERA and operated for 2 years as an independent cabinet-level agency under brain truster and political lightning rod Rexford Tugwell. In 1937, the president renamed the Resettlement Administration the Farm Security Administration and placed it in the more conservative Department of Agriculture. In 1943, as part of wartime restructuring, the War Food Administration assumed responsibility for the FSA migrant programs.[19] (For clarity, the acronym FSA is used throughout this essay.)

The FSA promoted marketing, farming, and equipment-buying farm cooperatives to help smaller and poorer producers compete in the agricultural marketplace. The agency also believed that these cooperatives would promote economic stability, enhance self-reliance, and foster local leadership. Pressure on the agency to maintain good loan repayment among its rehabilitation clients soon conflicted with the FSA's humanitarian thrust, and when it became clear that ill health was responsible for 50% of all loan defaults, the FSA moved into the field of health care delivery. As US Public Health Service senior surgeon and FSA chief medical officer Ralph C. Williams stated, "a family in good health was a better credit risk than a family in bad health."[20]

Medical Care Cooperatives

Williams told those attending the 1939 American Public Health Association convention that the FSA medical program was an "incidental by-product of a depression-born loan program for farm families unable to obtain credit elsewhere, and designed to accommodate a special economic group only."[21] This economic justification pacified vocal groups unsympathetic to the agency's social agenda, such as organized medicine, conservative politicians, and organized farm groups. However, Williams' public posture understated the powerful ideological commitment of the agency's medical hierarchy to make more public the practice of medicine. In line with the agency's cooperative philosophy, local FSA supervisors encouraged farmers to establish medical cooperatives. These supervisors asked local physicians to provide care to FSA clients in a group prepayment scheme to lower cost barriers and ensure access to needed medical care. Bundled into their annual loans, rehabilitation clients (also called borrowers) received a federal subsidy (typically around $35), which they then paid into a trustee-supervised fund. Participating physicians billed this fund, and if billings exceeded the amount set aside that month, doctors received prorated reimbursement. Flexibility at the local level was critical to the program's success with farmers and physicians alike. The policy of promoting cooperatives and local determination of local needs also fit into the FSA's commitment to participatory democracy. "Any plan in which the families unite to help themselves should reduce the cost of medical aid and thereby make more effective the funds thus expended [so that] a worthwhile beginning can be made by the families themselves toward better health."[22] Healthier clients made the task of supervision easier, and credit risks diminished as clients' health improved. This fact not only was a source of pride for the agency but was also critical to continued congressional support. Nearly 90% of all loans were eventually repaid in full. The FSA plans were also a new source of income for hard-pressed rural doctors. Participating doctors collected 65% of their fees from a group that had previously been able to pay little, if anything, for medical care.[23]

It was not the intent of the FSA in the medical cooperative program to fundamentally restructure the delivery of rural health services. Group prepayment was grafted onto traditional fee-for-service practice. Concessions of this sort, along with the fact that physicians' participation was voluntary and the extension of care was limited to a specified low-income group, made the FSA programs palatable to financially strapped rural practitioners. Still, the agency's promotion of consumer

participation on the cooperatives' governing boards, the key fiscal and administrative role played by the FSA, and the lowering of cost and access barriers for low-income farmers represent genuine reforms for the era. Of equal importance, the medical care cooperative program gave the FSA experience it put to good use as it extended its health programs to migrant workers and experimented with more radical proposals.

Migrant Health Programs

The New Deal confronted the problem of migrant labor in the United States in early 1935 when the California state emergency relief administration built two farm labor camps, using federal and state rural rehabilitation funds. The mobility of the migrants made direct payments for medical care administratively cumbersome. Consequently, in 1937 the FSA devised a bold alternative means of providing medical services: Agricultural Workers Health Associations (AWHAs). By 1946, seven regional AWHAs were providing medical services in 250 federal migrant camps nationwide.

The FSA developed its first AWHA in California and Arizona following a tour of the region by Dr Ralph C. Williams. Shocked at the appalling health conditions of migrant families, Williams called for the creation of a "state-wide incorporated health association . . . to make direct payments to doctors and hospitals for medical and hospital treatment."[24] Williams wisely enlisted the support of leaders in the California Medical Association. In 1937, the FSA gave $1 million to the newly incorporated Agricultural Workers Health and Medical Association. California and Arizona physicians made their uneasy alliance with the government, mindful of the swelling tide of social and political support for medical care reform:

> There have been theoretical objections and charges that such plans are a step toward "State Medicine," "compulsory sickness insurance" or "socialized medicine." In evaluating such objections, it may be well to consider alternatives. News . . . reveals almost parallel movements . . . in the direction of greater intervention of government in medical care. [S]tatements of President Roosevelt and the Social Security Board officials [and] the effort of some hospital insurance plans to invade the field of medical practice . . . are portents of a trend in the United States. It is doubtful if head on opposition can greatly affect this trend.[25]

As was true with the medical care cooperatives, local FSA representatives, typically camp managers, recruited physicians into the AWHAs. AWHA doctors rendered services at agreed-upon fees and the AWHA paid them directly. Physicians' participation was voluntary, and the physicians insisted that the migrants have free choice in selecting their physicians. Full-time public health nurses staffed the camp clinics and referred patients to participating physicians' offices when necessary. Physicians also held clinic hours at specified times of the week and received payment on a per diem, hourly, or—occasionally—salaried basis. Whenever possible, the AWHAs used existing community hospitals as referral centers for their sickest migrants. At Eleven Mile Corner, Ariz, and Belle Glade, Fla, the FSA took the extraordinary step of owning and operating hospitals for its migrant clients.[26]

FSA district and regional medical officers showed pragmatism and flexibility in adapting the AWHAs to local needs and exigencies. Medical societies influenced but did not dictate the setting of fee schedules and limits of coverage, and they could even express grievances on staffing matters to FSA medical officers. For their part, FSA district and regional medical officers maintained liaisons with county and state medical societies, supervised the field medical and nursing personnel, and implemented public health policies whose influence often extended beyond the camps' perimeters. Considerable local autonomy resulted in substantial variations in the organization and character of the migrant health programs. In California, migrants were mainstreamed into local physicians' offices, while elsewhere camp medical clinics were the preferred sites for medical care. FSA programs occasionally became sources of care for nonmigrant FSA rehabilitation clients. Despite local variations, the structure and philosophy of the AWHAs were consistent from region to region: available and adequate medical services, government subsidization of costs, and a focus on preventive services, particularly for pregnant women and children.

By negotiating fee schedules, granting physicians substantial freedom in medical decision making, and making the programs voluntary, the FSA successfully used a strategy that was repeated in many subsequent battles over health care reform. Even more than its medical care cooperative program, the FSA's promotion of an organizational and fiscal entity such as the AWHA to provide access to health care signified a major shift in federal health policy. Using the AWHA as a surrogate payer preserved the appearance of independence upon which doctors insisted while effectively undermining physicians' opposition to more overt government involvement in medical care financing or delivery.

Resettlement Projects

One of the FSA's more controversial efforts was the creation of a series of resettlement projects and greenbelt communities throughout the country (e.g., Greenbelt, Md). Under the resettlement program, low-income farmers, sharecroppers, and farm laborers living in the resettlement "homesteads" were given housing, a small plot of land for personal use, and technical advice on cooperative farming and marketing. The federal government's promotion of the resettlement projects embroiled the FSA in a political maelstrom from which it never fully extricated itself. Critics charged that land redistribution and agricultural cooperative programs were proof that the FSA had been "vaccinated by the Tugwellian virus [and] placed into the hands and under the blight of social gainers, do-gooders, bleeding hearts, and long-hairs who make a career of helping others for a price and according to their own particular, screwball ideas."[27]

Resettlement projects provided on-site care by general practitioners, although there was a wide mix of hospital, dental, and specialist care. The FSA established health clinics staffed by full-time salaried nurses and either full-time or part-time salaried physicians in at least 40 resettlement projects. Often, resettlement communities formed incorporated health associations similar to the AWHAs and contracted with local physicians, hospitals, and dentists for discounted services. Archival evidence, although anecdotal, provides support for the benefits of the program. In 1939, the FSA's chief medical officer found that "the families require less care now than they did 2 years ago, that they abuse their privileges very little, that they call him early in illness, that he enjoys making repeat calls without feeling it a burden on the families, and that the general Farm Security Administration program has already shown results in healthier families, particularly the children."[28]

Statewide Prepaid Plans

Perhaps no other region suffered the effects of the devastating drought of the 1930s more than North Dakota and South Dakota, two states where virtually everyone qualified for relief. In August 1936, alarm over rapidly deteriorating health conditions in the region prompted a meeting of local, state, and federal officials, including Surgeon General Thomas Parran, the WPA, the US Children's Bureau, the FSA, and organized medical groups of both states. Within a year, the FSA established two statewide capitated medical care plans in the drought-stricken Dakotas. The North Dakota and South Dakota Mutual Aid Corporations provided home and office medical care, hospitalization, major surgery, emergency dental care, nursing care, and drugs. The fee schedule was nearly 30% less than the prevailing minimums. Prevention and maternal and child services were integral components of these statewide programs, and the Mutual Aid Corporations even promoted clinical practice guidelines such as "an agreed minimum number of prenatal visits, delivery in the home or hospital, and necessary post-natal care."[29] Despite the fact that they received 60% of their billings, physicians opposed the prorating of bills so vigorously that the two statewide medical care experiments ended after 2 years of stormy operation.[30]

Experimental Rural Health Programs

Although the medical care programs and the AWHAs represented the most extensive and successful of all FSA medical care efforts, the agency undertook demonstration projects that were far more controversial. These experimental health programs went significantly beyond what agency leaders considered to be limitations of the earlier and more established programs for rehabilitation borrowers and migrant workers. In these earlier efforts, voluntary enrollment—insisted upon by physicians—led to an adverse selection effect. Families most likely to use services enrolled in the group payment programs while healthier families preferentially opted out of the group payment plans in favor of traditional fee-for-service arrangements. Certainly, pressure from local physicians strongly influenced this trend. Yet despite strenuous educational efforts by the FSA, the economic advantage of paying in advance for medical care, regardless of anticipated need, remained a difficult concept for many farmers. In response to this trend, the FSA considered alternative ways of improving the actuarial soundness of group medical care plans. The FSA developed experimental rural health programs to resolve this dilemma. Fiscal stability was achievable, the agency argued, by distributing the costs of illness over a broader patient base through countywide medical care plans with no income restrictions. Agency leaders also believed this strategy could promote higher reimbursements for physicians while allowing yearly membership fees to be income-adjusted and moderate, thereby generating broader community support.

Beginning in 1942, the FSA selected seven rural counties with an interest in medical care, reasonably stable income, sufficient medical and hospital facilities, and receptive local physicians. Of cardinal importance was the FSA's preference for counties with full-time public health units. This criterion was a reflection of the long-standing relationship between the FSA and the Public Health Service. Indeed, many of the leading figures in the medical care experiments of the FSA were Public Health Service officers who shared that agency's commitment to bringing public health back into the heart of medical care delivery. The experimental health programs adopted a sliding-scale membership fee, and the government subsidized the remaining costs. This federal support was necessary to enable lower-income families to participate and to allow the programs to include preventive services, hospitalization, drug costs, and dental work. The FSA created six rural health services (as they were generally called) in Texas (Wheeler and Cass counties), Mississippi (Newton County), Nebraska (Hamilton County), Arkansas (Nevada County), Georgia (Walton County), and New Mexico (Taos County). An even more ambitious six-county experimental health program was begun in southeastern Missouri.

The services provided by the experimental health programs reflected the FSA's consistent public health and primary care orientation. General practitioner services included office, home, and hospital visits. Surgical or subspecialty consultation was available with a referral by the general practitioner. Dental services covered not only emergency care but also routine and prophylactic treatment. All seven programs initially covered drug expenses. The experimental health programs maintained the characteristic flex-

ibility of the FSA medical care programs. Membership fees based on ability to pay, voluntary choice of available physicians, broad scope of services, voluntary participation by physicians and farmers alike, and local administration were constants. However, financing mechanisms varied and included modified fee-for-service plans, capitation, and full- or part-time salaried medical staff.[31]

Acceptance of these experimental programs was generally high among rural families eligible for participation, and membership as a percentage of population in the first year of operation ranged from 32% to 74%. Turnover remained a serious problem, however, sometimes reaching 50% per year.[32] When queried about their lack of ongoing interest, farmers usually cited the high membership costs of the program and their feeling that they were not receiving the services for which they had paid. Members were often unaware that the federal government subsidized most of the programs' costs, and the FSA found that out-of-pocket payments for medical care, alternative healers, and drugs were common. Although the experimental health programs were explicitly designed for a broad cross-section of the community, the public's perception that they were for disadvantaged farmers was hard to eradicate. Doctors reinforced this perception and discouraged middle-income families from joining.[33]

Few credible data on whether the experimental health programs had a beneficial effect on members' health exist. Basic vital statistics at that time were notoriously inaccurate, particularly in rural areas. It was also an era when few questioned the assumption that more medical care resulted in improved health:

> More mothers are now receiving prenatal and postnatal care, and better medical care and more hospitalization at childbirth. Patients are going to a doctor oftener and earlier, and are making more use of hospitalization facilities. Many families reported an increased feeling of security.[34]

Viewed in this light, the experimental health programs and the FSA program in toto were successful by commonly accepted measures, such as number of physician visits, hospitalization rates, number of prenatal visits, number of physician-attended or hospital births, and immunization rates. Experimental health program members received, on average, 2.6 physician visits per year, double the number cited by the Committee on the Costs of Medical Care for rural citizens. Prior to the establishment of the Nevada County program, only 10% of White women in the county delivered in hospitals, although nearly 90% were attended by a physician. In sharp contrast, Blacks delivered at home 99% of the time, nearly all attended by midwives or experienced neighbors. After the experimental program began, 50% of White babies and more than 25% of Black babies were born in the local hospital, while the percentage of physician-attended births for Blacks climbed to 75%.[35] Similar dramatic changes in obstetrical practice occurred in Taos County, which had a predominantly Spanish-speaking population. The annual number of hospitalizations for delivery in the fledgling Blue Cross plans was 107 per 1000 members, compared with 155 per 1000 in the experimental health programs.[36]

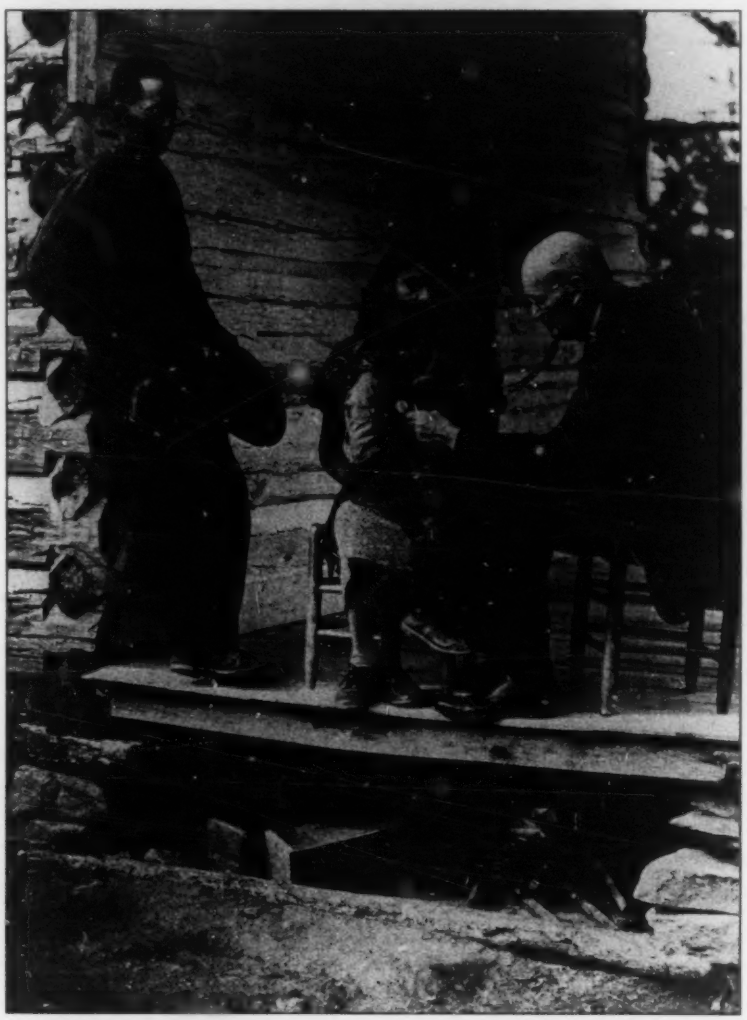
The experimental health programs were born of the conviction of FSA leaders that major structural and financial changes in America's health care system were imminent. A 1944 poll found that 68% of Americans supported an extension of Social Security to cover medical care and hospitalization; 89% felt that some people did not get medical care because of cost barriers; and 33% had themselves deferred treatment for financial reasons.[37] Many ranking FSA medical officers firmly believed that the nation would eventually adopt some form of national health insurance. These leaders believed that the experimental health programs afforded an unparalleled opportunity to gain practical experience in operating what might become a model for a future national system of medical care delivery. Former FSA chief medical officer Frederick D. Mott and his former assistant Milton I. Roemer wrote in 1948 that the experimental program had "given us what is probably an unmatched body of experience in the possible achievements and deficiencies of the tax-assisted and voluntary health insurance plans in rural areas."[38]

The experimental health programs experienced many of the same problems that beset earlier FSA health care delivery programs. The perception that the programs were for the indigent, reinforced by physicians who discouraged higher-income families from signing up, and the high turnover rate among families who used fewer services adversely affected the programs' actuarial soundness. The drain of younger, more able-bodied rural citizens to the armed services and urban-based defense industries left behind groups—women, children, and the elderly—with higher than average health care utilization, further exacerbating the adverse selection effect. Although professional misgivings were evident early on, many physicians supported the plans with the understanding that "the proposed association would in no way interfere with physicians in the practice of medicine and that patients would have free choice of physicians."[39]

The Medical Profession's Response

The reasons behind the FSA's initial success in recruiting rural practitioners are worth examining. First, the FSA's explicit goal was to provide medical care for a low-income population that was severely straining local medical resources. While doctors worried about the potential of the FSA programs in terms of a broader federal health agenda, the plans provided timely financial relief to hard-pressed rural general practitioners, driving them into a temporary alliance despite opposition by the American Medical Association. Free choice of physician, voluntary participation by client and practitioner alike, and control over matters of medical practice were core elements in the FSA health program. The FSA dealt only with medical doctors or their representatives, excluding osteopaths, chiropractors, midwives, and other folk practitioners. This policy strengthened the government's hand with the highly vocal and well-organized medical profession, the group whose authority over the practice of medicine was approved of by a public increasingly convinced of the benefits of scientific medicine.

At the center of the FSA plans were primary care practitioners, both physicians and nurses. This emphasis was crucial to the programs' successes for more than a decade. While not without its pragmatic side (after all, the majority of physicians available to the agency in rural areas were general practitioners), this strategy mirrored the convictions of the FSA medical leadership and harkened back to the recommendations of the Committee on the Costs of Medical Care. Well before World War II, the complementary forces of specialization and centralization were undercutting the central presence of the general practitioner in American medicine. Thus, the FSA programs bolstered the flagging financial and professional fortunes of the rural general-



Caswell County, North Carolina, 1940. Photograph by Marion Post Wolcott, from the Library of Congress, Prints and Photographs Division, FSA Historical Division (LC-USF 34-56376-D).

ist and provided doctors with a powerful, if potentially worrisome, ally in the profession's emerging sovereignty over medical practice.

Local, regional, and national politics influenced physicians' receptivity to the FSA plans. Statements that the plans violated medical ethics and the sanctity of the physician–patient relationship were commonplace. Many county and state medical societies, and invariably the American Medical Association, preferred the status quo to any government-sponsored health insurance program. As late as 1938, editors of many state medical journals mouthed official American Medical Association policy: "These are problems for local and state consideration . . . rather than problems of federal responsibility."[40] While physicians who supported the plans defended their position in the *Journal of the American Medical Association* and state medical journals, many doctors vociferously contended that the plans provided inferior care and that "medical services did not lend [themselves] to cooperative handling."[41] Clearly, medical care plans based on anything but the traditional fee-for-service engendered significant distrust among physicians. Even at the county level, where support for the FSA programs was most deep rooted, conflicts invariably emerged. Physicians charged above the established fee schedule, collected fees on the side, and double billed—all in violation of their agreements with the FSA. Physicians pressured rehabilitated families to cancel their membership, since a family that had paid off its debt was "no longer in need and [could] afford to purchase medical services privately."[42] Finally, many physicians responded to the prorating of bills by limiting service rather than increasing their attention to prevention, as the agency had naively expected. Doctors preferred strict definitions of medical eligibility, while the FSA's eligibility criteria and definitions of medical need were generous. For physicians, the laxity of the FSA's eligibility criteria, exemplified by the use of the AWHA camp medical clinics by nonindigent local residents, was an omen of a more threatening, unstated federal agenda.

Tension between the government's advocacy on behalf of low-income rural Americans and the medical profession's desire to control the practice of medicine eventually threatened the uneasy alliance that promoted the federal programs. Conflicts over the composition of supervisory boards, eligibility criteria, and, of course, payment were continuous. World War II's effect on already scarce rural medical manpower, the shifting funding priorities of Congress, and a growing political backlash against the social agenda of the New Deal exacerbated many of these conflicts. The impressive growth of the FSA health program notwithstanding, difficulties were evident even in the earliest stages of the FSA's involvement in health care. From 1938 on, termination of medical cooperatives accelerated, although the program peaked in terms of membership in 1942.[43] Powerful and deeply felt ideological positions within the medical profession had as much to do with the eventual dismantling of the medical care programs as the disruption caused by the war.[44]

The Great Depression marked a significant shift in the locus of charity and public welfare programs from philanthropists and local government to the federal government. The 1935 Social Security Act and other New Deal social legislation irreversibly broadened the federal government's responsibility for social welfare in America. While the American Medical Association stressed throughout the Depression that the care of indigents was a local concern, powerful financial and humanitarian concerns temporarily over-

rode physicians' traditional ideological opposition. Many local physicians and state medical societies accepted the FSA's role as a fiscal, organizational, and administrative intermediary. This schism certainly promoted the remarkable growth and development of the FSA's health programs. The threat of national health insurance drove constituent medical societies and individual practitioners to consider alternative methods of financing and delivering medical care.

The suspicions voiced by physicians that the FSA programs were a harbinger of a federalized health care system were not mere professional paranoia, nor were they inconsistent with many readily apparent facts. FSA leaders anticipated fundamental changes in the nation's health care system, and many in Washington expected the vast experience gained in the FSA plans to shape these reforms. FSA leaders actively participated in the deliberations of the Interdepartmental Committee for Health and Welfare Activities that supported the expansion of public health services and grants-in-aid to states for hospital construction, programs for the medically needy, and state-based general medical care programs. The committee's recommendations led directly to the 1938 National Health Conference. Soon after this conference, the American Medical Association reversed its long-standing opposition to voluntary health insurance in an extraordinary emergency meeting of its house of delegates.[45] In 1942 the FSA took a leading role in the Interbureau Committee for Post-War Programs in Agriculture, charged by the president to develop "all possible phases of a health program for the entire farm population now."[46] The FSA's ownership of two hospitals, its promotion of salaried and clinic-based practices, and its experimental health programs testify to agency leaders' interest in pushing the boundaries of federal involvement in health care delivery. The frequent use of Public Health Service officers to provide, administer, and organize rural medical services—an early harbinger of the National Health Service Corps—is further evidence of this agenda. In 1946 a youthful New Deal senator from Florida, Claude Pepper, noted in particular that the experimental health plans, "based on the tax-assisted voluntary health association principle, constitute a series of experiments of interest to the whole Nation. They are particularly important at this time, when our whole future national health policy is being decided."[47] Dr Mott confirmed Senator Pepper's views, saying that the experimental health plans "hold lessons for every rural community and for urban as well as rural Americans . . . [a]t a time when the nation is facing its health problems, weighing possible solutions, and rapidly approaching the stage of long-needed action."[48] It was with conscious deliberation that the agency downplayed this more progressive agenda during the evolutionary phase of the medical care plans.

Events in Europe and increasing fiscal and political conservatism in Congress profoundly altered the reform spirit characteristic of the early Roosevelt presidency. Between 1942 and 1946, the FSA embarked on a number of creative efforts to stave off criticism, such as having its nurses conduct Red Cross first aid programs. These efforts ultimately proved unsuccessful. The FSA was unable to withstand the attacks of conservative farm organizations and congressional opponents who had long waited to eviscerate the agency. In 1947, the FSA was transmutated into the far meeker Farmers Home Administration. Simultaneous with these developments, the allegiance of physicians shifted to groups antagonistic to the FSA's reform agenda. Dr Mott's warning in a confidential memorandum to his staff that an "unholy alliance" between the American Medical Association and the Farm Bureau could undermine the FSA health programs proved valid.[49] For example, in 1946 the California Medical Association abrogated its agreement with the FSA in favor of a group insurance program sponsored by the Farm Bureau and the Grange, two groups whose antipathy to the FSA was well known.[50]

Factors operating on a national scale were catalysts in the decline of the FSA's political fortunes. The war economy's beneficial impact on physicians' income and the scarcity of medical personnel resulting from the draft lessened the economic incentives that had previously generated flexibility on the part of doctors.[51] Stiffening resistance to further federal encroachment into medical care delivery was evident in physicians' initial opposition to the Emergency Maternal, Infant and Child Act.[52] The stumbling momentum toward national health insurance further crippled the agency, whose medical leaders were by then openly in support of a comprehensive national health program. The difficulties faced by the FSA medical leadership since the program's inception were evident in Dr Mott's response to a request to present his agency's position on the 1943 Wagner-Murray-Dingell national health insurance bill. The request, wrote Dr Mott confidentially to his colleagues, "raises an important question about the dilemma—which is not new to any of us—that of working for certain goals privately and yet having to take carefully considered stands publicly."[53] Indeed, as a matter of political and pragmatic expediency, FSA medical leaders downplayed their support of national health insurance. Privately, they remained optimistic that the FSA experience would move a national health program forward, although their optimism went unrewarded.[54]

Conclusion

The experience of the FSA health program yields insights into the often uncomfortable relationship between medicine and the federal government during periods of health care debate. Historically, the medical profession has been loath to place itself at the forefront of health care reforms. However, under financial duress, carried in the wake of a nationwide spirit of social reform, and undoubtedly faced with interventions that appeared inevitable, physicians played a vital role in the FSA health care program. Left to their own impulses and freed from the coercive effect of economic distress, they renewed their traditional opposition to federal involvement in health care. Although the FSA program expanded until World War II, physicians' dissatisfaction with and nonrenewal or outright abrogation of agreements accelerated from 1938 forward. Ultimately, physicians remained wary of third-party intermediaries and willingly allied themselves with the organized farm groups who were the architects of the FSA's demise.

The federal government's foray into health care delivery was not a wasted effort. By intervening directly in the provision of medical care services for underserved civilian populations, the government established a broad precedent. Not until the passage of Medicare and Medicaid, the creation of the Office of Economic Opportunity, and the neighborhood health center movement during the Kennedy-Johnson era would such a vast number of poor Americans gain access to medical care through lowered cost barriers. The economic and humanitarian factors that promoted the FSA's program are of central importance. Certainly, hundreds of thousands of rural Americans experienced their first regular source

of medical care and received immunizations, nutritional advice, and physical nurture within the friendly, if paternalistic, embrace of the federal government. By participating in FSA plans, physicians served both their financial and their more noble goals. Both physicians and clients experienced firsthand the role that fiscal and administrative intermediaries could play in the traditionally sacrosanct doctor–patient relationship. Postwar history shows that it was the private sector and not the federal government that benefited most from this initiation process.[55]

The agency's interdisciplinary approach to providing services demonstrates its public health and primary care orientation. The FSA's plans were centrally financed but organizationally decentralized. Since they revolved around the provision of care by generalists, they ran counter to the prevailing direction of American medicine. The plans reinforced the professional and economic security of rural general practitioners. The FSA's routine incorporation of such supposedly recent health care innovations as the primary care gatekeeper, the use of nurses as physician extenders, and preventive service was also a notable accomplishment and reflects an early federal experiment in managed care. Finally, many at the time believed that the FSA experience would shape a national health insurance plan that they believed was imminent. Congressional hearings on national health policy and the visible and active role given to the FSA medical hierarchy in postwar health care planning substantiate this view.

Although it was not the focus of this essay, the FSA's influence rippled well beyond the 12 years of the agency's existence. Many public health–oriented physicians who worked in the FSA program went on to shape future health care reforms, both in the United States and abroad. Dr Mott moved to Saskatchewan in 1945 and helped mold its provincial health care plan, which was the model for Canada's national health care system. The progressive movement in medicine and public health, programs such as the United Mine Workers Health and Welfare Fund, and the Office of Economic Opportunity owe a debt to such luminaries as Milton Roemer, Loren Kerr, George Silver, Sy Axelrod, Les Falk, Joseph Mountin, Martha May Eliot, Henry Makover, and many others with ties to the FSA.[56] As Dr Mott wrote to his dispirited colleagues from his vantage point in Canada, "We can have the satisfaction of spearheading a movement which will ultimately benefit every citizen. . . . [O]ur consolation can be that we played an historic role at a time when pioneering was urgently needed."[57]

The FSA medical care program remains one of the earliest, most extensive, and certainly most comprehensive federal efforts in health care delivery. It incorporated precepts usually considered more contemporary, such as consumer participation, decentralization of care, centralization of payment source, and an abiding focus on prevention and health education. Strategies that controlled costs, such as the use of nurse clinicians, salaried physicians, and administrative controls on referrals and hospitalization, all speak to the agency's prescient approach to health care delivery. Finally, the FSA provided hundreds of thousands of rural families with their first taste of insurance-based medical care. One participant believes that the FSA experience helped spur the dramatic postwar growth of the private health insurance industry in rural America.[58]

The FSA experience illuminates many characteristics of American medicine that are relevant to the current health care policy debate. Its historical importance as the most extensive New Deal foray into health care delivery notwithstanding, the experiment foreshadowed or directly influenced various health care delivery models in this country and abroad. Forces that contributed to the FSA's remarkable growth and eventual demise provide insight into the role of government and physicians in health care reform. Universal health insurance has resurfaced on our nation's political agenda. The FSA experience, seen as a dry run for a national health program, undermines the myth that government cannot play a creative, fiscally responsible, and professionally acceptable role in health care financing and delivery. □

47. BAE report, iii.
48. Ibid., xix.
49. Frederick D. Mott to health services staff, October 11, 1945. File 31-9, Mott papers.
50. Jesse B. Yaukey to Frederick D. Mott, December 22, 1946; see also U.S. Department of Agriculture, Farm Security Administration, *Annual Report of the Chief Medical Officer, Fiscal Year Ending June 30, 1945.* File 46-19, Mott papers.
51. Mott and Roemer took the position in their monograph that the loss of physician manpower and the loss of farmers to the armed services and war industries were the primary causes of the program's decline. See Mott and Roemer, *Rural Health and Medicine,* 406–407. I have argued that these forces accelerated that program's demise but that the loss of physicians' financial incentive to participate was of equal importance. See Grey, "Poverty, Politics, and Health."
52. *Journal of the American Medical Association,* organizational section, 129 (1945): 1185.
53. Frederick D. Mott to health services staff, October 11, 1945. File 31-9, Mott papers.
54. Frederick D. Mott to health services staff, November 25, 1943. File 31-9, Mott papers.
55. This issue is covered well in Starr, *The Social Transformation,* 310–334.
56. As part of my research on the FSA, I interviewed 12 individuals who participated in the FSA health programs. Many of these individuals went on to prominent positions in the public health community and participated in the social reforms that occurred in the 1960s and 1970s. Readers interested in the role that Loren Kerr played in the United Mine Workers Health and Welfare Fund are referred to Allen Derickson, "The United Mine Workers of America and the Recognition of Occupational Respiratory Diseases, 1902–1968," *American Journal of Public Health* 81 (1991):782–790. The link between FSA programs and the Office of Economic Opportunity's programs is explored in Richard Couto, *Ain't Gonna Let Nobody Push Me Around: The Pursuit of Racial Justice in the Rural South* (Philadelphia, Pa.: Temple University Press, 1991).
57. Frederick D. Mott to Jesse B. Yaukey, March 27, 1947. File 46-19, Mott papers.
58. Milton Roemer, interview with author, Seattle, Washington, October 1987.
